Preface to the second edition  
Organic chemistry and this book

### 1 What is organic chemistry?
- Organic chemistry and you  
- Organic compounds  
- Organic chemistry and industry  
- Organic chemistry and the periodic table  
- Organic chemistry and this book  
- Further reading

### 2 Organic structures
- Hydrocarbon frameworks and functional groups  
- Drawing molecules  
- Hydrocarbon frameworks  
- Functional groups  
- Carbon atoms carrying functional groups can be classified by oxidation level  
- Naming compounds  
- What do chemists really call compounds?  
- How should you name compounds?  
- Further reading

### 3 Determining organic structures
- Introduction  
- Mass spectrometry  
- Mass spectrometry detects isotopes  
- Atomic composition can be determined by high-resolution mass spectrometry  
- Nuclear magnetic resonance  
- Regions of the $^{13}$C NMR spectrum  
- Different ways of describing chemical shift  
- A guided tour of the $^{13}$C NMR spectra of some simple molecules  
- The $^1$H NMR spectrum  
- Infrared spectra  
- Mass spectra, NMR, and IR combined make quick identification possible  
- Double bond equivalents help in the search for a structure  
- Looking forward to Chapters 13 and 18  
- Further reading

### 4 Structure of molecules
- Introduction  
- Electrons occupy atomic orbitals  
- Molecular orbitals—diatomic molecules  
- Bonds between different atoms  
- Hybridization of atomic orbitals  
- Rotation and rigidity  
- Conclusion  
- Looking forward  
- Further reading

### 5 Organic reactions
- Chemical reactions  
- Nucleophiles and electrophiles  
- Curly arrows represent reaction mechanisms  
- Drawing your own mechanisms with curly arrows  
- Further reading

### 6 Nucleophilic addition to the carbonyl group
- Molecular orbitals explain the reactivity of the carbonyl group  
- Attack of cyanide on aldehydes and ketones  
- The angle of nucleophilic attack on aldehydes and ketones  
- Nucleophilic attack by ‘hydride’ on aldehydes and ketones  
- Addition of organometallic reagents to aldehydes and ketones  
- Addition of water to aldehydes and ketones  
- Hemiacetal from reaction of alcohols with aldehydes and ketones  
- Ketones also form hemiacetals  
- Acid and base catalysis of hemiacetal and hydrate formation  
- Bisulfite addition compounds  
- Further reading

### 7 Delocalization and conjugation
- Introduction  
- The structure of ethene (ethylene, CH$_2$=CH$_2$)  
- Molecules with more than one C=C double bond

---

</tbody>
</table>
Diastereoisomers are stereoisomers that are not enantiomers.
Chiral compounds with no stereogenic centres.
Axes and centres of symmetry.
Separating enantiomers is called resolution.

Further reading

15 Nucleophilic substitution at saturated carbon
Mechanisms for nucleophilic substitution.
How can we decide which mechanism ($S_N1$ or $S_N2$) will apply to a given organic compound?
A closer look at the $S_N1$ reaction.
A closer look at the $S_N2$ reaction.
Contrasts between $S_N1$ and $S_N2$.
The leaving group in $S_N1$ and $S_N2$ reactions.
The nucleophile in $S_N1$ reactions.
The nucleophile in the $S_N2$ reaction.
Nucleophiles and leaving groups compared.
Looking forward: elimination and rearrangement reactions.
Further reading

16 Conformational analysis
Bond rotation allows chains of atoms to adopt a number of conformations.
Conformation and configuration.
Barriers to rotation.
Conformations of ethane.
Conformations of propane.
Conformations of butane.
Ring strain.
A closer look at cyclohexane.
Substituted cyclohexanes.
To conclude...
Further reading

17 Elimination reactions
Substitution and elimination.
How the nucleophile affects elimination versus substitution.
$E1$ and $E2$ mechanisms.
Substrate structure may allow $E1$.
The role of the leaving group.
$E1$ reactions can be stereoselective.
$E2$ eliminations have anti-periplanar transition states.
The regioselectivity of $E2$ eliminations.
Anion-stabilizing groups allow another mechanism—$E1cB$.
To conclude.
Further reading

18 Review of spectroscopic methods
There are three reasons for this chapter.
Spectroscopy and carbonyl chemistry.
Acid derivatives are best distinguished by infrared.
Small rings introduce strain inside the ring and higher s character outside it.
Simple calculations of $C=O$ stretching frequencies in IR spectra.
NMR spectra of alkenes and small rings.
Proton NMR distinguishes axial and equatorial protons in cyclohexanes.
Interactions between different nuclei can give enormous coupling constants.
Identifying products spectroscopically.
Tables.
Shifts in proton NMR are easier to calculate and more informative than those in carbon NMR.
Further reading

19 Electrophilic addition to alkenes
Alkenes react with bromine.
Oxidation of alkenes to form epoxides.
Electrophilic addition to unsymmetrical alkenes is regioselective.
Electrophilic addition to dienes.
Unsymmetrical bromonium ions open regioselectively.
Electrophilic additions to alkenes can be stereospecific.
Adding two hydroxyl groups: dihydroxylation.
Breaking a double bond completely: periodate cleavage and ozonolysis.
Adding one hydroxyl group: how to add water across a double bond.
To conclude... a synopsis of electrophilic addition reactions.
Further reading

20 Formation and reactions of enols and enolates
Would you accept a mixture of compounds as a pure substance?
Tautomerism: formation of enols by proton transfer.
Why don’t simple aldehydes and ketones exist as enols?
Evidence for the equilibration of carbonyl compounds with enols 451
Enolization is catalysed by acids and bases 452
The intermediate in the base-catalysed reaction is an enolate ion 452
Summary of types of enol and enolate 454
Stable enols 456
Consequences of enolization 459
Reaction with enols or enolates as intermediates 460
Stable equivalents of enolate ions 465
Enol and enolate reactions at oxygen: preparation of enol ethers 467
Reactions of enol ethers 468
To conclude 470
Further reading 470

21 Electrophi lic aromatic substitution 471
Introduction: enols and phenols 471
Benzene and its reactions with electrophiles 473
Electrophilic substitution on phenols 479
A nitrogen lone pair activates even more strongly 482
Alkyl benzenes also react at the ortho and para positions 484
Electron-withdrawing substituents give meta products 486
Halogen 5: show evidence of both electron withdrawal and donation 489
Two or more substituents may cooperate or compete 491
Some problems and some opportunities 492
A closer look at Friedel–Crafts chemistry 492
Exploiting the chemistry of the nitro group 494
Summary 495
Further reading 497

22 Conjugate addition and nucleophilic aromatic substitution 498
Alkenes conjugated with carbonyl groups 498
Conjugated alkenes can be electrophilic 499
Summary: factors controlling conjugate addition 509
Extending the reaction to other electron-deficient alkenes 510
Conjugate substitution reactions 511
Nucleophilic epoxidation 513
Nucleophilic aromatic substitution 514
The addition–elimination mechanism 515
The $S_{n}1$ mechanism for nucleophilic aromatic substitution: diazonium compounds 520
The benzene mechanism 523
To conclude… 526
Further reading 527

23 Chemoselectivity and protecting groups 528
Selectivity 528
Reducing agents 530
Reduction of carbonyl groups 530
Hydrogen as a reducing agent: catalytic hydrogenation 534
Getting rid of functional groups 539
Dissolving metal reductions 541
Selectivity in oxidation reactions 544
Competing reactivity: choosing which group reacts 546
A survey of protecting groups 549
Further reading 561

24 Regioselectivity 562
Introduction 562
Regioselectivity in electrophilic aromatic substitution 563
Electrophilic attack on alkenes 570
Regioselectivity in radical reactions 571
Nucleophilic attack on allylic compounds 574
Electrophilic attack on conjugated dienes 579
Conjugate addition 581
Regioselectivity in action 582
Further reading 583

25 Alkylation of enolates 584
Carbonyl groups show diverse reactivity 584
Some important considerations that affect all alkylations 584
Nitriles and nitroalkanes can be alkylated 585
Choice of electrophile for alkylation 587
Lithium enolates of carbonyl compounds 587
Alkylation of lithium enolates 588
Using specific enol equivalents to alkylate aldehydes and ketones 591
Alkylation of β-dicarbonyl compounds 595
Ketone alkylation poses a problem in regioselectivity 598
Enones provide a solution to regioselectivity problems 601
Using Michael acceptors as electrophiles 605
To conclude… 612
Further reading 613

26 Reactions of enolates with carbonyl compounds: the aldol and Claisen reactions 614
Introduction 614
The aldol reaction 615
Cross-condensations 618
Specific enol equivalents can be used to control aldol reactions 624
How to control aldol reactions of esters 631
How to control aldol reactions of aldehydes 632
How to control aldol reactions of ketones 634
Intramolecular aldol reactions 636
Acylation at carbon 640
Crossed ester condensations 643
Summary of the preparation of keto-esters by the Claisen reaction 647
Controlling acylation with specific enol equivalents 648
Intramolecular crossed Claisen ester condensations 652
Carbonyl chemistry—where next? 654
Further reading 654

Preface to the second edition

Students of chemistry are not hard-pressed to find a text to support their learning in organic chemistry through their years at university. The shelves of a university bookshop will usually offer a choice of at least half a dozen—all entitled ‘Organic Chemistry’, all with substantially more than 1000 pages. Closer inspection of these titles quickly disappoints expectations of variety. Almost without exception, general organic chemistry texts have been written to accompany traditional American sophomore courses, with their rather precisely defined requirements. This has left the authors of these books little scope for reinvigorating their presentation of chemistry with new ideas.

We wanted to write a book whose structure grows from the development of ideas rather than being dictated by the sequential presentation of facts. We believe that students benefit most of all from a book which leads from familiar concepts to unfamiliar ones, not just encouraging them to know but to understand and to understand why. We were spurred on by the nature of the best modern university chemistry courses, which themselves follow this pattern: this is after all how science itself develops. We also knew that if we did this we could, from the start, relate the chemistry we were talking about to the two most important sorts of chemistry that exist—the chemistry that is known as life, and the chemistry as practised by chemists solving real problems in laboratories.

We aimed at an approach which would make sense to and appeal to today’s students. But all of this meant taking the axe to the roots of some long-standing textbook traditions. The best way to find out how something works is to take it apart and put it back together again, so we started with the tools for expressing chemical ideas: structural diagrams and curly arrows. Organic chemistry is too huge a field to learn even a small part by rote, but with these tools, students can soon make sense of chemistry which may be unfamiliar in detail by relating it to what they know and understand. By calling on curly arrows and ordering chemistry according to mechanism we allow ourselves to discuss mechanistically (and orbitally) simple reactions (addition to $\text{C}=$O, for example) before more complex and involved ones (such as $\text{S}_\text{N}1$ and $\text{S}_\text{N}2$).

Complexity follows in its own time, but we have deliberately omitted detailed discussion of obscure reactions of little value, or of variants of reactions which lie a simple step of mechanistic logic from our main story: some of these are explored in the problems associated with each chapter, which are available online.1 We have similarly aimed to avoid exhuming principles and rules (from those of Le Châtelier through Markovnikov, Saytseff, least motion, and the like) to explain things which are better understood in terms of unifying fundamental thermodynamic or mechanistic concepts.

All science must be underpinned by evidence, and support for organic chemistry’s claims is provided by spectroscopy. For this reason we first reveal to students the facts which spectroscopy tells us (Chapter 3) before trying to explain them (Chapter 4) and then use them to deduce mechanisms (Chapter 5). NMR in particular forms a significant part of four chapters in the book, and evidence drawn from NMR underpins many of the discussions right through the book. Likewise, the mechanistic principles we outline in Chapter 5, firmly based in the orbital theories of Chapter 4, underpin all of the discussion of new reactions through the rest of the book.

We have presented chemistry as something whose essence is truth, of provable veracity, but which is embellished with opinions and suggestions to which not all chemists subscribe. We aim to avoid dogma and promote the healthy weighing up of evidence, and on occasion we are content to leave readers to draw their own conclusions. Science is important not just to scientists, but to society. Our aim has been to write a book which itself takes a scientific

1 See www.oxfordtextbooks.co.uk/orc/clayden2e/.
standpoint—one foot inside the boundary of the known, the other just outside—and encourages the reader to do the same.

The authors are indebted to the many supportive and critical readers of the first edition of this book who have supplied us over the last ten years with a stream of comments and corrections, hearty encouragements and stern rebukes. All were carefully noted and none was overlooked while we were writing this edition. In many cases these contributions helped us to correct errors or make other improvements to the text. We would also like to acknowledge the support and guidance of the editorial team at OUP, and again to recognize the seminal contribution of the man who first nurtured the vision that organic chemistry could be taught with a book like this, Michael Rodgers. The time spent on the preparation of this edition was made available only with the forbearance of our families, friends and research groups, and we thank all of them for their patience and understanding.

Changes for this edition

In the decade since the publication of the first edition of this book it has become clear that some aspects of our original approach were in need of revision, some chapters in need of updating with material which has gained in significance over those years, and others in need of shortening. We have taken into account a consistent criticism from readers that the early chapters of the first edition were too detailed for new students, and have made substantial changes to the material in Chapters 4, 8, and 12, shifting the emphasis towards explanation and away from detail more suitably found in specialised texts. Every chapter has been rewritten to improve clarity and new explanations and examples have been used widely. The style, location, and content of the spectroscopy chapters (3, 13, 18, and 31) have been revised to strengthen the links with material appearing nearby in the book. Concepts such as conjugate addition and regioselectivity, which previously lacked coherent presentation, now have their own chapters (22 and 24). In some sections of the first edition, groups of chapters were used to present related material: these chapter groups have now been condensed—so, for example, Chapters 25 and 26 on enolate chemistry replace four previous chapters, Chapters 31 and 32 on cyclic molecules replace three chapters, Chapter 36 on rearrangements and fragmentations replaces two chapters, and Chapter 42 on the organic chemistry of life replaces three chapters (the former versions of which are available online). Three chapters placed late in the first edition have been moved forward and revised to emphasize links between their material and the enolate chemistry of Chapters 25 and 26, thus Chapter 27 deals with double-bond stereocontrol in the context of organo-main group chemistry, and Chapters 29 and 30, addressing aromatic heterocycles, now reinforce the link between many of the mechanisms characteristic of these compounds and those of the carbonyl addition and condensation reactions discussed in the previous chapters. Earlier discussion of heterocycles also allows a theme of cyclic molecules and transition states to develop throughout Chapters 29–36, and matches more closely the typical order of material in undergraduate courses.

Some fields have inevitably advanced considerably in the last 10 years: the chapters on organometallic chemistry (40) and asymmetric synthesis (41) have received the most extensive revision, and are now placed consecutively to allow the essential role of organometallic catalysis in asymmetric synthesis to come to the fore. Throughout the book, new examples, especially from the recent literature of drug synthesis, have been used to illustrate the reactions being discussed.

---

Organic chemistry and this book

You can tell from the title that this book tells you about organic chemistry. But it tells you more than that: it tells you how we know about organic chemistry. It tells you facts, but it also teaches you how to find facts out. It tells you about reactions, and teaches you how to predict which reactions will work; it tells you about molecules, and it teaches you how to work out ways of making them.

We said ‘it tells’ in that last paragraph. Maybe we should have said ‘we tell’ because we want to speak to you through our words so that you can see how we think about organic chemistry and to encourage you to develop your own ideas. We expect you to notice that three people have written this book, and that they don’t all think or write in the same way. That is as it should be. Organic chemistry is too big and important a subject to be restricted by dogmatic rules. Different chemists think in different ways about many aspects of organic chemistry and in many cases it is not yet, and may never be, possible to be sure who is right. In many cases it doesn’t matter anyway.

We may refer to the history of chemistry from time to time but we are usually going to tell you about organic chemistry as it is now. We will develop the ideas slowly, from simple and fundamental ones using small molecules to complex ideas and large molecules. We promise one thing. We are not going to pull the wool over your eyes by making things artificially simple and avoiding the awkward questions. We aim to be honest and share both our delight in good complete explanations and our puzzlement at inadequate ones.

The chapters

So how are we going to do this? The book starts with a series of chapters on the structures and reactions of simple molecules. You will meet the way structures are determined and the theory that explains those structures. It is vital that you realize that theory is used to explain what is known by experiment and only then to predict what is unknown. You will meet mechanisms—the dynamic language used by chemists to talk about reactions—and of course some reactions.

The book starts with an introductory section of four chapters:

1. What is organic chemistry?
2. Organic structures
3. Determining organic structures
4. Structure of molecules

Chapter 1 is a ‘rough guide’ to the subject—it will introduce the major areas where organic chemistry plays a role, and set the scene by showing you some snapshots of a few landmarks. In Chapter 2 you will look at the way in which we present diagrams of molecules on the printed page. Organic chemistry is a visual, three-dimensional subject and the way you draw molecules shows how you think about them. We want you too to draw molecules in the best way possible. It is just as easy to draw them well as to draw them in an old-fashioned or inaccurate way.

Then in Chapter 3, before we come to the theory which explains molecular structure, we shall introduce you to the experimental techniques which tell us about molecular structure. This means studying the interactions between molecules and radiation by spectroscopy—using the whole electromagnetic spectrum from X-rays to radio waves. Only then, in Chapter 4, will we go behind the scenes and look at the theories of why atoms combine in the ways they do. Experiment comes before explanation. The spectroscopic methods of Chapter 3 will still be telling the truth in a hundred years’ time, but the theories of Chapter 4 will look quite dated by then.
We could have titled those three chapters:

2. What shapes do organic molecules have?
3. How do we know they have those shapes?
4. Why do they have those shapes?

You need to have a grasp of the answers to these three questions before you start the study of organic reactions. That is exactly what happens next. We introduce organic reaction mechanisms in Chapter 5. Any kind of chemistry studies reactions—the transformations of molecules into other molecules. The dynamic process by which this happens is called mechanism and is the grammar of organic chemistry—the way that one molecule can change into another. We want you to start learning and using this language straight away so in Chapter 6 we apply it to one important class of reaction. We therefore have:

5. Organic reactions
6. Nucleophilic addition to the carbonyl group

Chapter 6 reveals how we are going to subdivide organic chemistry. We shall use a mechanistic classification rather than a structural classification and explain one type of reaction rather than one type of compound in each chapter. In the rest of the book most of the chapters describe types of reaction in a mechanistic way. Here is a selection from the first half of the book:

9. Using organometallic reagents to make C–C bonds
10. Nucleophilic substitution at the carbonyl group
11. Nucleophilic substitution at C=O with loss of carbonyl oxygen
15. Nucleophilic substitution at saturated carbon
17. Elimination reactions
19. Electrophilic addition to alkenes
20. Formation and reactions of enols and enolates
21. Electrophilic aromatic substitution
22. Conjugate addition and nucleophilic aromatic substitution

Interspersed with these chapters are others on physical aspects of molecular structure and reactivity, stereochemistry, and structural determination, which allow us to show you how we know what we are telling you is true and to explain reactions intelligently.

7. Delocalization and conjugation
8. Acidity, basicity, and pK_a
12. Equilibria, rates, and mechanisms
13. 1H NMR: proton nuclear magnetic resonance
14. Stereochemistry
16. Conformational analysis
18. Review of spectroscopic methods

By the time we reach the end of Chapter 22 you will have met most of the important ways in which organic molecules react with one another, and we will then spend two chapters revisiting some of the reactions you have met before in two chapters on selectivity: how to get the reaction you want to happen and avoid the reaction you don’t.

23. Chemoselectivity and protecting groups
24. Regioselectivity

The materials are now in place for us to show you how to make use of the reaction mechanisms you have seen. We spend four chapters explaining some ways of using carbonyl chemistry and the chemistry of Si, S, and P to make C–C and C=C bonds. We then bring this all together with a chapter which gives you the tools to work out how you might best set about making any particular molecule.
25. Alkylation of enolates
26. Reactions of enolates with carbonyl compounds: the aldol and Claisen reactions
27. Sulfur, silicon, and phosphorus in organic chemistry
28. Retrosynthetic analysis

Most organic compounds contain rings, and many cyclic structures entail one of two aspects which are rather special: aromaticity and well-defined conformations. The next group of chapters leads you through the chemistry of ring-containing compounds to the point where we have the tools to explain why even acyclic molecules react to give products with certain spatial features.

29. Aromatic heterocycles 1: reactions
30. Aromatic heterocycles 2: synthesis
31. Saturated heterocycles and stereoelectronics
32. Stereoselectivity in cyclic molecules
33. Diastereoselectivity

We said that Chapter 22 marks the point where most of the important ways in which molecules react together have been introduced—most but not all. For the next section of the book we survey a range of rather less common but extremely important alternative mechanisms, finishing with a chapter that tells you how we can find out what mechanism a reaction follows.

34. Pericyclic reactions 1: cycloadditions
35. Pericyclic reactions 2: sigmatropic and electrocyclic reactions
36. Participation, rearrangement, and fragmentation
37. Radical reactions
38. Synthesis and reactions of carbenes
39. Determining reaction mechanisms

The last few chapters of the book take you right into some of the most challenging roles that organic chemistry has been called on to play, and in many cases tell you about chemistry discovered only in the last few years. The reactions in these chapters have been used to make the most complex molecules ever synthesized, and to illuminate the way that organic chemistry underpins life itself.

40. Organometallic chemistry
41. Asymmetric synthesis
42. Organic chemistry of life
43. Organic chemistry today

‘Connections’ sections

That’s a linear list of 43 chapters, but chemistry is not a linear subject! It is impossible to work through the whole field of organic chemistry simply by starting at the beginning and working through to the end, introducing one new topic at a time, because chemistry is a network of interconnecting ideas. But, unfortunately, a book is, by nature, a beginning-to-end sort of thing. We have arranged the chapters in a progression of difficulty as far as is possible, but to help you find your way around we have included at the beginning of each chapter a ‘Connections’ section. This tells you three things divided among three columns:

(a) The ‘Building on’ column: what you should be familiar with before reading the chapter—in other words, which previous chapters relate directly to the material within the chapter.
(b) The ‘Arriving at’ column: a guide to what you will find within the chapter.
(c) The ‘Looking forward to’ column: signposting which chapters later in the book fill out and expand the material in the chapter.
The first time you read a chapter, you should really make sure you have read any chapter mentioned under (a). When you become more familiar with the book you will find that the links highlighted in (a) and (c) will help you see how chemistry interconnects with itself.

Boxes and margin notes

The other things you should look out for throughout the text are the margin notes and boxes. There are four sorts:

- The most important box looks like this. Anything in this sort of box is a key concept or a summary. It's the sort of thing you would do well to hold in your mind as you read or to note down as you learn.

- Boxes like this will contain additional examples, amusing background information, and similar interesting, but maybe inessential, material. The first time you read a chapter, you might want to miss out this sort of box, and only read them later on to flesh out some of the main themes of the chapter.

Online support

Organic structures and organic reactions are three-dimensional (3D), and as a complement to the necessarily two-dimensional representations in this book we have developed a comprehensive online resource to allow you to appreciate the material in three dimensions. ChemTube3D contains interactive 3D animations and structures, with supporting information, for some of the most important topics in organic chemistry, to help you master the concepts presented in this book. Online resources are flagged on the pages to which they relate by an icon in the margin. Each web page contains some information about the reaction and an intuitive interactive reaction scheme that controls the display. 3D curly arrows indicate the reaction mechanism, and the entire sequence from starting materials via transition state to products is displayed with animated bond-breaking and forming, and animated charges and lone pairs. The entire process is under the control of you, the user, and can be viewed in three dimensions from any angle. The resizable window button produces a larger window with a range of control options and the molecular photo booth allows you to make a permanent record of the view you want.

ChemTube3D uses Jmol to display the animations so users can interact with the animated 3D structures using the pop-up menu or console using only a web browser. It is ideal for personalized learning and open-ended investigation is possible. We suggest that you make use of the interactive resources once you have read the relevant section of the book to consolidate your understanding of chemistry and enhance your appreciation of the importance of spatial arrangements.

Substantial modifications were made in the writing of this new edition, including the loss or contraction of four chapters found towards the end of the first edition. To preserve this material for future use, the following four chapters from the first edition are available for download from the book’s website at www.oxfordtextbooks.co.uk/orc/clayden2e/:

- The chemistry of life
- Mechanisms in biological chemistry
- Natural products
- Polymerization
Further reading

At the end of each chapter, you may find yourself wanting to know more about the material it covers. We have given a collection of suggested places to look for this material—other books, or reviews in the chemical literature, or even some original research papers. There are thousands of examples in this book, and in most cases we have not directed you to the reports of the original work—this can usually be found by a simple electronic database search. Instead, we have picked out publications which seem most interesting, or relevant. If you want an encyclopaedia of organic chemistry, this is not the book for you. You would be better turning to one such as March's Advanced Organic Chemistry (M. B. Smith and J. March, 6th edn, Wiley, 2007), which contains thousands of references.

Problems

You can’t learn all of organic chemistry—there’s just too much of it. You can learn trivial things like the names of compounds but that doesn’t help you understand the principles behind the subject. You have to understand the principles because the only way to tackle organic chemistry is to learn to work it out. That is why we have provided problems, which you can access from the book’s web site. They are to help you discover if you have understood the material presented in each chapter.

If a chapter is about a certain type of organic reaction, say elimination reactions (Chapter 19), the chapter itself will describe the various ways (‘mechanisms’) by which the reaction can occur and it will give definitive examples of each mechanism. In Chapter 19 there are three mechanisms and about 60 examples altogether. You might think that this is rather a lot but there are in fact millions of examples known of these three mechanisms and Chapter 19 barely scrapes the surface. The problems will help you make sure that your understanding is sound, and that it will stand up to exposure to the rigours of explaining real-life chemistry.

In general, the 10–15 problems at the end of each chapter start easy and get more difficult. They come in two or three sorts. The first, generally shorter and easier, allow you to revise the material in that chapter. They might revisit examples from the chapter to check that you can use the ideas in familiar situations. The next few problems might develop specific ideas from different parts of the chapter, asking you, for example, why one compound reacts in one way while a similar one behaves quite differently. Finally, you will find some more challenging problems asking you to extend the ideas to unfamiliar molecules, and, especially later in the book, to situations which draw on the material from more than one chapter.

The end-of-chapter problems should set you on your way but they are not the end of the journey to understanding. You are probably reading this text as part of a university course and you should find out what kind of examination problems your university uses and practise them too. Your tutor will be able to advise you on suitable problems to help you at each stage of your development.

The solutions manual

The problems would be of little use to you if you could not check your answers. For maximum benefit, you need to tackle some or all of the problems as soon as you have finished each chapter without looking at the answers. Then you need to compare your suggestions with ours. You will find our suggestions in the accompanying solutions manual, where each problem is discussed in some detail. (You can buy the solutions manual separately from this book.) The purpose of the problem is first stated or explained. Then, if the problem is a simple one, the answer is given. If the problem is more complex, a discussion of possible answers follows with some comments on the value of each. There may be a reference to the source of the problem so that you can read further if you wish.
**Colour**

If you have flicked forward through the pages of this book, you will already have noticed something unusual: almost all of the chemical structures are shown in red. This is quite intentional: emphatic red underlines the message that structures are more important than words in organic chemistry. But sometimes small parts of structures are in other colours: here are two examples from p. 12, where we talk about organic compounds containing elements other than C and H.

Why are the atom labels black? Because we wanted them to stand out from the rest of the molecule. In general you will see black used to highlight the important details of a molecule—they may be the groups taking part in a reaction, or something that has changed as a result of the reaction, as in these examples from Chapters 9 and 17.

We shall often use black to emphasize ‘curly arrows’, devices that show the movement of electrons, and whose use you will learn about in Chapter 5. Here are examples from Chapters 11 and 22: notice black also helps the ‘+’ and ‘−’ charges to stand out.

Occasionally, we shall use other colours, such as green, orange, or brown, to highlight points of secondary importance. This example is part of a reaction taken from Chapter 19: we want to show that a molecule of water (H₂O) is formed. The green atoms show where the water comes from. Notice black curly arrows and a new black bond.

Other colours come in when things get more complicated—in this Chapter 21 example, we want to show two possible outcomes of a reaction: the brown and the orange arrows show the two alternatives, with the green highlighting the deuterium atom remaining in both cases.
And, in Chapter 14, colour helps us highlight the difference between carbon atoms carrying four different groups and those with only three different groups. The message is: if you see something in a colour other than red, take special note—the colour is there for a reason.

Amino acids are chiral except glycine—plane of paper is a plane of symmetry through C, N, and CO$_2$H.
What is organic chemistry?

Organic chemistry and you

You are already a highly skilled organic chemist. As you read these words, your eyes are using an organic compound (retinal) to convert visible light into nerve impulses. When you picked up this book, your muscles were doing chemical reactions on sugars to give you the energy you needed. As you understand, gaps between your brain cells are being bridged by simple organic molecules (neurotransmitter amines) so that nerve impulses can be passed around your brain. And you did all that without consciously thinking about it. You do not yet understand these processes in your mind as well as you can carry them out in your brain and body. You are not alone there. No organic chemist, however brilliant, understands the detailed chemical working of the human mind or body very well.

We, the authors, include ourselves in this generalization, but we are going to show you in this book what enormous strides have been taken in the understanding of organic chemistry since the science came into being in the early years of the nineteenth century. Organic chemistry began as a tentative attempt to understand the chemistry of life. It has grown into the confident basis of worldwide activities that feed, clothe, and cure millions of people without their even being aware of the role of chemistry in their lives. Chemists cooperate with physicists and mathematicians to understand how molecules behave and with biologists to understand how interactions between molecules underlie all of life. The enlightenment brought by chemistry in the twentieth century amounted to a revolution in our understanding of the molecular world, but in these first decades of the twenty-first century the revolution is still far from complete. We aim not to give you the measurements of the skeleton of a dead science but to equip you to understand the conflicting demands of an adolescent one.

Like all sciences, chemistry has a unique place in our pattern of understanding of the universe. It is the science of molecules. But organic chemistry is something more. It literally creates itself as it grows. Of course we need to study the molecules of nature both because they are interesting in their own right and because their functions are important to our lives. Organic chemistry has always been able to illuminate the mechanisms of life by making new molecules that give information not available from the molecules actually present in living things.

This creation of new molecules has given us new materials such as plastics to make things with, new dyes to colour our clothes, new perfumes to wear, new drugs to cure diseases. Some people think some of these activities are unnatural and their products dangerous or unwholesome. But these new molecules are built by humans from other molecules found naturally on earth using the skills inherent in our natural brains. Birds build nests; people build houses. Which is unnatural? To the organic chemist this is a meaningless distinction. There are toxic compounds and nutritious ones, stable compounds and reactive ones—but there is only one type of chemistry: it goes on both inside our brains and bodies, and also in our flasks and reactors, born from the ideas in our minds and the skill in our hands. We are not going to set ourselves up as moral judges in any way. We believe it is right to try and understand the world

11-cis-retinal absorbs light and allows vision

serotonin human neurotransmitter

We are going to illustrate this chapter with the structures of the organic compounds we talk about. If you do not understand the diagrams, just read the text. Explanation of the rest is on its way.
about us as best we can and to use that understanding creatively. This is what we want to share with you.

**Organic compounds**

Organic chemistry started as the chemistry of life, when that was thought to be different from the chemistry in the laboratory. Then it became the chemistry of carbon compounds, especially those found in coal. But now it is both. It is the chemistry of the compounds formed by carbon and other elements such as are found in living things, in the products of living things, and wherever else carbon is found.

The most abundant organic compounds are those present in living things and those formed over millions of years from dead things. In earlier times, the organic compounds known from nature were those in the ‘essential oils’ that could be distilled from plants and the alkaloids that could be extracted from crushed plants with acid. Menthol is a famous example of a flavouring compound from the essential oil of spearmint and *cis*-jasmine an example of a perfume distilled from jasmine flowers.

Natural products have long been used to cure diseases, and in the sixteenth century one became famous—quinine was extracted from the bark of the South American cinchona tree and used to treat fevers, especially malaria. The Jesuits who did this work (the remedy was known as ‘Jesuit’s bark’) did not of course know what the structure of quinine was, but now we do. More than that, the molecular structure of quinine has inspired the design of modern drug molecules which treat malaria much more effectively than quinine itself.

The main reservoir of chemicals available to the nineteenth century chemists was coal. Distillation of coal to give gas for lighting and heating (mainly hydrogen and carbon monoxide) also gave a brown tar rich in aromatic compounds such as benzene, pyridine, phenol, aniline, and thiophene.

Phenol was used in the nineteenth century by Lister as an antiseptic in surgery, and aniline became the basis for the dyestuffs industry. It was this that really started the search for new organic compounds made by chemists rather than by nature. In 1856, while trying to make quinine from aniline, an 18-year old British chemist, William Perkin, managed to produce a mauve residue, mauveine, which revolutionized the dyeing of cloth and gave birth to the synthetic dyestuffs industry. A related dyestuff of this kind—still available—is Bismarck Brown: much of the early work on dyes was done in Germany.

In the twentieth century oil overtook coal as the main source of bulk organic compounds so that simple hydrocarbons like methane (CH₄, ‘natural gas’), propane, and butane (CH₃CH₂CH₃ and CH₃CH(CH₃)CH₃, ‘calor gas’ or LPG) became available for fuel. At the same time chemists began the search for new molecules from new sources such as fungi, corals, and bacteria, and two organic chemical industries developed in parallel—‘bulk’ and
‘fine’ chemicals. Bulk chemicals like paints and plastics are usually based on simple molecules produced in multitonne quantities while fine chemicals such as drugs, perfumes, and flavouring materials are produced in smaller quantities but much more profitably.

At the time of writing there were over 16 million organic compounds known. How many more might there be? Even counting only moderately sized molecules, containing fewer than about 30 carbon atoms (about the size of the mauveine structure above), it has been calculated that something in the region of $1,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000,000$, stable compounds are possible. There aren’t enough carbon atoms in the universe to make them all.

Among the 16 million that have been made, there are all kinds of molecules with amazingly varied properties. What do they look like? They may be crystalline solids, oils, waxes, plastics, elastics, mobile or volatile liquids, or gases. Familiar ones include sugar, a cheap natural compound isolated from plants as hard white crystals when pure, and petrol, a mixture of colourless, volatile, flammable hydrocarbons. Isooctane is a typical example and gives its name to the octane rating of petrol.

The compounds need not lack colour. Indeed we can soon dream up a rainbow of organic compounds covering the whole spectrum, not to mention black and brown. In this table we have avoided dyestuffs and have chosen compounds as varied in structure as possible.

Colour is not the only characteristic by which we recognize compounds. All too often it is their odour that lets us know they are around. There are some quite foul organic compounds too; the infamous stench of the skunk is a mixture of two thiols—sulfur compounds containing SH groups.

But perhaps the worst smell ever recorded was that which caused the evacuation of the German city of Freiburg in 1889. Attempts to make thioacetone by the cracking of trithioacetone gave rise to ‘an offensive smell which spread rapidly over a great area of the town causing fainting, vomiting, and a panic evacuation...the laboratory work was abandoned’.

It was perhaps foolhardy for workers at an Esso research station to repeat the experiment of cracking trithioacetone south of Oxford in 1967. Let them take up the story. ‘Recently we found ourselves with an odour problem beyond our worst expectations. During early experiments, a stopper jumped from a bottle of residues, and, although replaced at once, resulted in an immediate complaint of nausea and sickness from colleagues working in a building two hundred yards away. Two of our chemists who had done no more than investigate the cracking of minute amounts of thioacetone found themselves the object of hostile stares in a restaurant and suffered the humiliation of having a waitress spray the area around them with a deodorant. The odours defied the expected effects of dilution since workers in the laboratory did not find the odours intolerable ... and genuinely denied responsibility since they were working in closed systems. To convince them otherwise, they were dispersed with other observers around the laboratory, at distances up to a quarter of a mile, and one drop of either acetone gem-dithiol or the mother liquors from crude thioacetone crystallizations were placed on a watch glass in a fume cupboard. The odour was detected downwind in seconds.’

There are two candidates for this dreadful smell—propane dithiol (called acetone gem-dithiol above) or 4-methyl-4-sulfanylpentan-2-one. It is unlikely that anyone else will be brave enough to resolve the controversy.

But nasty smells have their uses. The natural gas piped into homes contains small amounts of deliberately added sulfur compounds such as tert-butyl thiol (CH₃)₃CSH. When we say small, we mean very small—humans can detect one part in 50,000,000,000 parts of natural gas.

Other compounds have delightful odours. To redeem the honour of sulfur compounds we must cite the truffle, whose pigs can smell through a metre of soil and whose taste and smell is so delightful that truffles cost more than their weight in gold. Damascenones are responsible for the smell of roses. If you smell one drop you will be disappointed, as it smells rather like turpentine or camphor, but next morning you, and the clothes you were wearing, will smell powerfully of roses. Many smells develop on dilution.

Humans are not the only creatures with a sense of smell. We can find mates using all our senses, but insects cannot do this. They are small in a crowded world and they find those of the opposite sex of their own species by smell. Most insects produce volatile compounds that can be picked up by a potential mate in incredibly weak concentrations. Only 1.5 mg of serricornin, the sex pheromone of the cigarette beetle, could be isolated from 65,000 female beetles—so there isn’t much in each beetle. Nevertheless, the slightest whiff of it causes the males to gather and attempt frenzied copulation. The sex pheromone of the beetle Popilia japonica, also given off by the females, has been made by chemists. As little as 5 μg (micrograms, note!) was more effective than four virgin females in attracting the males.

The pheromone of the gypsy moth, disparlure, was identified from a few μg isolated from the moths: as little as 2 × 10⁻¹² g is active as a lure for the males in field tests. The three pheromones we have mentioned are available commercially for the specific trapping of these destructive insect pests.
Don’t suppose that the females always do all the work; both male and female olive flies produce pheromones that attract the other sex. The remarkable thing is that one mirror image of the molecule attracts the males while the other attracts the females! Mirror image isomers of a molecule called frontalin are also emitted by male elephants; female elephants can tell the age and appeal of a potential mate from the amount of each isomer he produces.

What about taste? Take the grapefruit. The main flavour comes from another sulfur compound and human beings can detect $2 \times 10^{-5}$ parts per billion of this compound. This is an almost unimaginably small amount equal to $10^{-4}$ mg per tonne or a drop, not in a bucket, but in a fairly large lake. Why evolution should have left us so extraordinarily sensitive to grapefruit, we leave you to imagine.

For a nasty taste, we should mention ‘bittering agents’, put into dangerous household substances like toilet cleaner to stop children drinking them by accident. Notice that this complex organic compound is actually a salt—it has positively charged nitrogen and negatively charged oxygen atoms—and this makes it soluble in water.

Other organic compounds have strange effects on humans. Various ‘drugs’ such as alcohol and cocaine are taken in various ways to make people temporarily happy. They have their dangers. Too much alcohol leads to a lot of misery and any cocaine at all may make you a slave for life.

Again, let’s not forget other creatures. Cats seem to be able to go to sleep anywhere, at any time. This surprisingly simple compound, isolated from the cerebrospinal fluid of cats, appears to be part of their sleep-control mechanism. It makes them, or rats, or humans fall asleep immediately.
This compound and disparlure (above) are both derivatives of fatty acids. Fatty acids in the diet are a popular preoccupation, and the good and bad qualities of saturates, monounsaturates, and polyunsaturates are continually in the news: one of the many dietary molecules reckoned to have demonstrable anticancer activity is CLA (conjugated linoleic acid), which is found in dairy products and also, most abundantly, you may be interested to know, in kangaroo meat.

Resveratrole is another dietary component with beneficial effects: it may be responsible for the apparent ability of red wine to prevent heart disease. It is a quite different sort of organic compound, with two benzene rings.

For a third edible molecule, how about vitamin C? This is an essential factor in your diet—that is why it is called a vitamin—and in the diet of other primates, guinea-pigs, and fruit bats (other mammals possess the biochemical machinery to make it themselves). The disease scurvy, a degeneration of soft tissues from which sailors on the long voyages of past centuries suffered, results from a lack of vitamin C. It also is a universal antioxidant, scavenging for rogue reactive radicals and protecting damage to DNA. Some people think an extra large intake may even protect against the common cold.

**Organic chemistry and industry**

Vitamin C is manufactured on a huge scale by Roche, a Swiss company. All over the world there are chemistry-based companies making organic molecules on scales varying from a few kilograms to thousands of tonnes per year. This is good news for students of organic chemistry: knowing how molecules behave and how to make them is a skill in demand, and it is an international job market.

The petrochemicals industry consumes huge amounts of crude oil: the largest refinery in the world, in Jamnagar, India, processes 200 million litres of crude oil every day. An alarmingly large proportion of this is still just burnt as fuel, but some of it is purified or converted into organic compounds for use in the rest of the chemical industry.

Some simple compounds are made both from oil and from plants. The ethanol used as a starting material to make other compounds in industry is largely made by the catalytic hydration of ethylene from oil. But ethanol is also used as a fuel, particularly in Brazil, where it is made by fermentation of sugar cane. Plants are extremely powerful organic chemical factories (with sugar cane being among the most efficient of all of them). Photosynthesis extracts carbon dioxide directly from the air and uses solar energy to reduce it to form less oxygen-rich organic compounds from which energy can be re-extracted by combustion. Biodiesel is made in a similar way from the fatty acid components of plant oils.

Plastics and polymers take much of the production of the petrochemical industry in the form of monomers such as styrene, acrylates, and vinyl chloride. The products of this enormous industry are everything made of plastic, including solid plastics for household goods and furniture, fibres for clothes (over 25 million tonnes per annum), elastic polymers for car tyres, light bubble-filled polymers for packing, and so on. Worldwide 100 million tonnes of polymers are made per year and PVC manufacture alone employs over 50,000 people to make over 20 million tonnes per year.

Many adhesives work by polymerization of monomers, which can be applied as a simple solution. You can glue almost anything with ‘superglue’, a polymer of methyl cyanoacrylate.

Washing-up bowls are made of the polymer polyethylene but the detergent you put in them belongs to another branch of the chemical industry—companies like Unilever and Procter and Gamble produce detergent, cleaners, bleaches, and polishes, along with soaps, gels, cosmetics, and shaving foams. These products may smell of lemon, lavender, or sandalwood but they too mostly come from the oil industry.

Products of this kind tend to underplay their petrochemical origins and claim affinity with the perceived freshness and cleanliness of the natural world. They also try to tell us, after a
fashion, what they contain. Try this example—the list of contents from a well-known brand of shower gel, which we are reassuringly told is ‘packed with natural stuff’ (including 10 ‘real’ lemons) and contains ‘100% pure and natural lemon and tea tree essential oils’.

It doesn’t all make sense to us, but here is a possible interpretation. We certainly hope this book will set you on the path of understanding the sense (and the nonsense!) of this sort of thing.

The particular detergents, surfactants, acids, viscosity controllers, and so on are chosen to blend together to give a smooth gel. The result should feel, smell, and look attractive and work as an effective detergent and shampoo (some of the compounds are added for their moisturizing and anti-electrostatic effect on hair). The yellow colour and lemon scent are considered fresh and clean by the customer. Several of the ingredients are added as pure compounds; the ones which aren’t are mixtures of isomers or polymers; the most impure are the mixtures of hydrocarbons referred to as the ‘pure and natural’ essential oils. Is it ‘packed with natural stuff’? Indeed it is. It all comes from natural sources, the principal one being decomposed carboniferous forests trapped for millions of years underground.

The coloration of manufactured goods is a huge business, with a range of intense colours required for dyeing cloth, colouring plastic and paper, painting walls, and so on. Leaders in this area are companies such as Akzo Nobel, which had sales of €14.6 bn in 2010. One of the most commonly used dyestuffs is indigo, an ancient dye that used to be isolated from plants but is now made from petrochemical feedstocks. It is the colour of blue jeans. More modern
dyestuffs can be represented by the benzodifuranones developed by ICI, which are used for colouring synthetic fabrics like polyesters (red), the phthalocyanine–metal complexes (typically blue or green), or the ‘high-performance’ red pigment DPP (1,4-diketopyrrolo[3,4-c]pyr-roles) series developed by Ciba-Geigy.

The scent of the shower gel above came from a mixture of plant extracts with the pure compound (in fact a mixture of two isomers) citral. The big fragrance and flavouring companies (such as Firmenich, International Flavors and Fragrances, and Givaudan) deal in both naturals and synthetics—‘naturals’ are mixtures of compounds extracted from plants—leaves, seeds, and flowers. ‘Synthetics’ are single compounds, sometimes present in plant-derived sources and sometime newly designed molecules, which are mixed with each other and with ‘naturals’ to build up a scent. A typical perfume will contain 5–10% fragrance molecules in an ethanol/water (about 90:10) mixture. So the perfumery industry needs a very large amount of ethanol and, you might think, not much perfumery material. In fact, important fragrances like jasmine are produced on a >10,000 tonnes per annum scale. The cost of a pure perfume ingredient like cis-jasmone (p. 2), the main ingredient of jasmine, may be several hundred pounds, dollars, or euros per gram.

**The world of perfumery**

Perfume chemists use extraordinary language to describe their achievements: ‘PacoRabanne pour homme was created to reproduce the effect of a summer walk in the open air among the hills of Provence: the smell of herbs, rosemary and thyme, and sparkling freshness with cool sea breezes mingling with warm soft Alpine air. To achieve the required effect, the perfumer blended herbaceous oils with woody accords and the synthetic aroma chemical dimethylheptanol, which has a penetrating but indefinable freshness associated with open air or freshly washed linen.’

Chemists produce synthetic flavourings such as ‘smoky bacon’ and even ‘chocolate’. Meaty flavours come from simple heterocycles such as alkyl pyrazines (present in coffee as well as roast meat) and furonol, originally found in pineapples. Compounds such as corylone and maltol give caramel and meaty flavours. Mixtures of these and other synthetic compounds can be ‘tuned’ to taste like many roasted foods from fresh bread to coffee and barbecued meat. Some flavouring compounds are also perfumes and may also be used as an intermediate in making other compounds. Vanillin is the main component of the flavour of vanilla, but is manufactured on a large scale for many other uses too.
Food chemistry includes much larger-scale items than flavours. Sweeteners such as sugar itself are isolated from plants on an enormous scale. You saw sucrose on p. 3, but other sweeteners such as saccharin (discovered in 1879!) and aspartame (1965) are made on a sizeable scale. Aspartame is a compound of two of the natural amino acids present in all living things and over 10,000 tonnes per annum are made by the NutraSweet company.

\[
\begin{align*}
\text{aspartame (‘NutraSweet’)} & \\

\end{align*}
\]

One of the great revolutions of modern life has been the expectation that humans will survive diseases because of a specifically designed treatment. In the developed world, people live to old age because infections which used to kill can now be cured or kept at bay. Antibiotics are our defence against bacteria, preventing them from multiplying. One of the most successful of these is Beecham amoxycillin, which was developed by SmithKline. The four-membered ring at the heart of the molecule is the β-lactam, which targets the disease-causing bacteria. Medicinal chemists also protect us from the insidious threat of viruses which use the body’s own biochemistry to replicate. Tamiflu is a line of defence against the ever-present danger of a flu epidemic, while ritonavir is one of the most advanced drugs designed to prevent replication of HIV and to slow down or prevent the onset of AIDS.

The story of Tamiflu and how the ingenuity of chemists ensures a constant supply is related at the other end of this book, in Chapter 43.

The best-selling current drugs are largely designed to address the human body’s own failings. Sales of Lipitor and Nexium both topped $5bn in 2009, figures which serve to illustrate the financial scale of developing safe and effective new treatments. Lipitor is one of the class of drugs known as statins, widely prescribed to control cholesterol levels in older people. Nexium is a proton pump inhibitor, which works to reduce peptic and duodenal ulcers. Sales of Glivec (developed by Novartis and introduced in 2001) are far smaller, but to those suffering from certain cancers such as leukaemia it can be a lifesaver.
We cannot maintain our present high density of population in the developed world, nor deal with malnutrition in the developing world unless we preserve our food supply from attacks by insects and fungi and from competition by weeds. The world market for agrochemicals produced by multinationals such as Bayer CropScience and Syngenta is over £10bn per annum divided between herbicides, fungicides, and insecticides.

Many of the early agrochemicals were phased out as they were persistent environmental pollutants. Modern agrochemicals have to pass stringent environmental safety tests. The most famous modern insecticides are modelled on the plant-derived pyrethrins, stabilized against degradation in sunlight by chemical modification (the brown and green portions of decamethrin) and targeted to specific insects on specific crops. Decamethrin has a safety factor of >10,000 for mustard beetles over mammals, can be applied at only 10 grams per hectare (about one level tablespoon per football pitch), and leaves no significant environmental residue.

As you learn more chemistry, you will appreciate how remarkable it is that Nature should produce the three-membered rings in these compounds and that chemists should use them in bulk compounds to be sprayed on crops in fields. Even more remarkable in some ways are the fungicides based on a five-membered ring containing three nitrogen atoms—the triazole ring. These compounds inhibit an enzyme present in fungi but not in plants or animals. Fungal diseases are a real threat: as in the Irish potato famine of the nineteenth century, the various fungal blights, blotches, rots, rusts, smuts, and mildews can overwhelm any crop in a short time.

**Organic chemistry and the periodic table**

All the compounds we have shown you are built up on hydrocarbon (carbon and hydrogen) skeletons. Most have oxygen and/or nitrogen as well; some have sulfur and some phosphorus, and maybe the halogens (F, Cl, Br, and I). These are the main elements of organic chemistry.
But organic chemistry has also benefited from the exploration of (some would say take-over bid for) the rest of the periodic table. The organic chemistry of silicon, boron, lithium, tin, copper, zinc, and palladium has been particularly well studied and these elements are common constituents of ‘organic’ reagents used in the laboratory. You will meet many of them throughout this book. Butyllithium, trimethylsilyl chloride, tributyltin hydride, diethylzinc, and lithium dimethylcuprate provide examples.

\[
\begin{align*}
&\text{butyllithium} & \text{trimethylsilyl chloride} & \text{tributyltin hydride} & \text{diethylzinc} & \text{lithium dimethylcuprate} \\
&\text{Li} & \text{Si} & \text{Sn} & \text{Zn} & \text{Cu} & \text{Li} \\
&\text{BuLi} & \text{Me₃SiCl} & \text{Bu₃SnH} & \text{Et₂Zn} & \text{Me₂CuLi} \\
\end{align*}
\]

The halogens also appear in many life-saving drugs. Antiviral compounds such as fialuridine (which contains both F and I, as well as N and O) are essential for the fight against HIV and AIDS. They are modelled on natural compounds from nucleic acids. The naturally occurring cytotoxic (antitumour) agent halomon, extracted from red algae, contains Br and Cl.

The organic chemist’s periodic table would have to emphasize all of these elements and more—the table below highlights most of those elements in common use in organic reactions. New connections are being added all the time—before the end of the last century the organic chemistry of ruthenium, gold, and samarium was negligible; now reagents and catalysts incorporating these metals drive a wide range of important reactions.

\[
\text{halomon—naturally occurring antitumour agent}
\]

So where does inorganic chemistry end and organic chemistry begin? Would you say that the antiviral compound foscarnet was organic? It is a compound of carbon with the formula CPO₅Na₃ but it has no C–H bonds. And what about the important reagent tetrakis (triphenylphosphine)palladium? It has lots of hydrocarbon—12 benzene rings in fact—but the benzene rings are all joined to phosphorus atoms that are arranged in a square around the central palladium atom, so the molecule is held together by C–P and P–Pd bonds, not by a hydrocarbon skeleton. Although it has the very organic-looking formula C₇₂H₆₀P₄Pd, many people would say it is inorganic. But is it?

\[
\text{foscarnet—antiviral agent}
\]

\[
\text{tetrakistriphenylphosphine palladium—important catalyst}
\]

\[
\text{[(C₆H₅)₃P]₄Pd}
\]

\[
\text{(Ph₃P)₄Pd}
\]
The answer is that we don’t know and we don’t care. Strict boundaries between traditional disciplines are undesirable and meaningless. Chemistry continues across the old boundaries between organic chemistry and inorganic chemistry, organic chemistry and physical chemistry or materials, or organic chemistry and biochemistry. Be glad that the boundaries are indistinct as that means the chemistry is all the richer. This lovely molecule (Ph₃P)₄Pd belongs to chemistry.

**Organic chemistry and this book**

We have told you about organic chemistry’s history, the types of compounds it concerns itself with, the things it makes, and the elements it uses. Organic chemistry today is the study of the structure and reactions of compounds in nature, of compounds in the fossil reserves such as coal and oil, and of those compounds that can be made from them. These compounds will usually be constructed with a hydrocarbon framework but will also often have atoms such as O, N, S, P, Si, B, halogens, and metals attached to them. Organic chemistry is used in the making of plastics, paints, dyestuffs, clothes, foodstuffs, human and veterinary medicines, agrochemicals, and many other things. Now we can summarize all of these in a different way.

- The main components of organic chemistry as a discipline are:
  - structure determination—how to find out the structures of new compounds even if they are available only in invisibly small amounts
  - theoretical organic chemistry—how to understand these structures in terms of atoms and the electrons that bind them together
  - reaction mechanisms—how to find out how these molecules react with each other and how to predict their reactions
  - synthesis—how to design new molecules, and then make them
  - biological chemistry—how to find out what Nature does and how the structures of biologically active molecules are related to what they do.

This book is about all these things. It is about the structures of organic molecules and the reasons behind those structures. It is about the shapes of these molecules and how the shape relates to their function, especially in the context of biology. It explains how these structures and shapes are discovered. It tells you about the reactions the molecules undergo and, more importantly, how and why they behave in the way they do. It tells you about nature and about industry. It tells you how molecules are made and how you too can think about making molecules.

This is the landscape through which you are about to travel. And, as with any journey to somewhere new, exciting, and sometimes challenging, the first thing is to make sure you have at least some knowledge of the local language. Fortunately the language of organic chemistry couldn’t be simpler: it’s all pictures. The next chapter will get us communicating.

**Further reading**

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at http://www.oxfordtextbooks.co.uk/orc/clayden2e/
There are over 100 elements in the periodic table. Many molecules contain well over 100 atoms—palytoxin (a naturally occurring compound with potential anticancer activity), for example, contains 129 carbon atoms, 221 hydrogen atoms, 54 oxygen atoms, and 3 nitrogen atoms. It’s easy to see how chemical structures can display enormous variety, providing enough molecules to build even the most complicated living creatures.
But how can we understand what seems like a recipe for confusion? Faced with the collection of atoms we call a molecule, how can we make sense of what we see? This chapter will teach you how to interpret organic structures. It will also teach you how to draw organic molecules in a way that conveys all the necessary information and none of the superfluous.

**Hydrocarbon frameworks and functional groups**

As we explained in Chapter 1, organic chemistry is the study of compounds that contain carbon. Nearly all organic compounds also contain hydrogen; most also contain oxygen, nitrogen, or other elements. Organic chemistry concerns itself with the way in which these atoms are bonded together into stable molecular structures, and the way in which these structures change in the course of chemical reactions.

Some molecular structures are shown below. These molecules are all amino acids, the constituents of proteins. Look at the number of carbon atoms in each molecule and the way they are bonded together. Even within this small class of molecules there’s great variety—glycine and alanine have only two or three carbon atoms; phenylalanine has nine.

![Amino acid structures](image)

Lysine has a chain of atoms; tryptophan has rings.

In methionine the atoms are arranged in a single chain; in leucine the chain is branched. In proline, the chain bends back on itself to form a ring.

Yet all of these molecules have similar properties—they are all soluble in water, they are all both acidic and basic (amphoteric), they can all be joined with other amino acids to form proteins. This is because the chemistry of organic molecules depends much less on the number or the arrangement of carbon or hydrogen atoms than on the other types of atoms (O, N, S, P, Si...) in the molecule. We call parts of molecules containing small collections of these other atoms functional groups, simply because they are groups of atoms that determine the way the molecule works. All amino acids contain two functional groups: an amino (NH$_2$ or NH) group and a carboxylic acid (CO$_2$H) group (some contain other functional groups as well).
That isn’t to say the carbon atoms aren’t important; they just play quite a different role from those of the oxygen, nitrogen, and other atoms they are attached to. We can consider the chains and rings of carbon atoms we find in molecules as their skeletons, which support the functional groups and allow them to take part in chemical interactions, much as your skeleton supports your internal organs so they can interact with one another and work properly.

We will see later how the interpretation of organic structures as hydrocarbon frameworks supporting functional groups helps us to understand and rationalize the reactions of organic molecules. It also helps us to devise simple, clear ways of representing molecules on paper. You saw these structural diagrams in Chapter 1, and in the next section we shall teach you ways to draw (and ways not to draw) molecules—the handwriting of chemistry. This section is extremely important because it will teach you how to communicate chemistry, clearly and simply, throughout your life as a chemist.

Drawing molecules

Be realistic

Below is another organic structure—again, you may be familiar with the molecule it represents; it is a fatty acid commonly called linoleic acid.

We could also depict linoleic acid as

or as
You may well have seen diagrams like these last two in older books—they used to be easy to print (in the days before computers) because all the atoms were in a line and all the angles were 90°. But are they realistic? We will consider ways of determining the shapes and structures of molecules in more detail in Chapter 3, but the picture below shows the structure of linoleic acid determined by X-ray crystallography.

![X-ray structure of linoleic acid](image)

You can see that the chain of carbon atoms is not linear, but a zig-zag. Although our diagram is just a two-dimensional representation of this three-dimensional structure, it seems reasonable to draw it as a zig-zag too.

This gives us our first guideline for drawing organic structures.

- **Guideline 1**
  
  Draw chains of atoms as zig-zags.

Realism of course has its limits—the X-ray structure shows that the linoleic acid molecule is in fact slightly bent in the vicinity of the double bonds; we have taken the liberty of drawing it as a 'straight zig-zag'. Similarly, close inspection of crystal structures like this reveals that the angle of the zig-zag is about 109° when the carbon atom is not part of a double bond and 120° when it is. The 109° angle is the ‘tetrahedral angle’, the angle between two vertices of a tetrahedron when viewed from its centre. In Chapter 4 we shall look at why carbon atoms take up this particular arrangement of bonds. Our realistic drawing is a projection of a three-dimensional structure onto flat paper so we have to compromise.

**Be economical**

When we draw organic structures we try to be as realistic as we can be without putting in superfluous detail. Look at these three pictures.

![Images of Mona Lisa](image)

(1) is immediately recognizable as Leonardo da Vinci’s Mona Lisa. You may not recognize (2)—it’s also Leonardo da Vinci’s Mona Lisa—this time viewed from above. The frame is very ornate, but the picture tells us as much about the painting as our rejected linear and 90° angle
diagrams did about our fatty acid. They’re both correct—in their way—but sadly useless. What we need when we draw molecules is the equivalent of (3). It gets across the idea of the original, and includes all the detail necessary for us to recognize what it’s a picture of, and leaves out the rest. And it was quick to draw—this picture was drawn in less than 10 minutes: we haven’t got time to produce great works of art!

Because functional groups are the key to the chemistry of molecules, clear diagrams must emphasize the functional groups and let the hydrocarbon framework fade into the background. Compare the diagrams below:

The second structure is the way that most organic chemists would draw linoleic acid. Notice how the important carboxylic acid functional group stands out clearly and is no longer cluttered by all those Cs and Hs. The zig-zag pattern of the chain is much clearer too. And this structure is much quicker to draw than any of the previous ones!

To get this diagram from the one above we’ve done two things. Firstly, we’ve got rid of all the hydrogen atoms attached to carbon atoms, along with the bonds joining them to the carbon atoms. Even without drawing the hydrogen atoms we know they’re there—we assume that any carbon atom that doesn’t appear to have its potential for four bonds satisfied is also attached to the appropriate number of hydrogen atoms. Secondly, we’ve rubbed out all the Cs representing carbon atoms. We’re left with a zig-zag line, and we assume that every kink in the line represents a carbon atom, as does the end of the line.

We can turn these two simplifications into two more guidelines for drawing organic structures.

- **Guideline 2**
  Miss out the Hs attached to carbon atoms, along with the C–H bonds (unless there is a good reason not to).

- **Guideline 3**
  Miss out the capital Cs representing carbon atoms (unless there is a good reason not to).

**Be clear**

Try drawing some of the amino acids represented on p. 16 in a similar way, using the three guidelines. The bond angles at tetrahedral carbon atoms are about 109°. Make them look about 109° projected on to a plane! (120° is a good compromise, and it makes the drawings look neat.)

Start with leucine—earlier we drew it as the structure to the right. Get a piece of paper and do it now. Once you have done this, turn the page to see how your drawing compares with our suggestions.
It doesn’t matter which way up you’ve drawn it, but your diagram should look something like one of these structures below.

The guidelines we gave were only guidelines, not rules, and it certainly does not matter which way round you draw the molecule. The aim is to keep the functional groups clear and let the skeleton fade into the background. That’s why the last two structures are all right—the carbon atom shown as ‘C’ is part of a functional group (the carboxyl group) so it can stand out.

Now turn back to p. 16 and try redrawing the some of the other eight structures there using the guidelines. Don’t look at our suggestions below until you’ve done them! Then compare your drawings with our suggestions.

Remember that these are only suggestions, but we hope you’ll agree that this style of diagram looks much less cluttered and makes the functional groups much clearer than the diagrams on p. 16. Moreover, they still bear significant resemblance to the ‘real thing’—compare these crystal structures of lysine and tryptophan with the structures shown above, for example.
Structural diagrams can be modified to suit the occasion

You’ll probably find that you want to draw the same molecule in different ways on different occasions to emphasize different points. Let’s carry on using leucine as an example. We mentioned before that an amino acid can act as an acid or as a base. When it acts as an acid, a base (for example hydroxide, OH\(^{-}\)) removes H\(^{+}\) from the carboxylic acid group in a reaction we can represent as:

\[
\text{H} \quad \text{O} \quad \text{NH}_2 \quad \text{H} \quad \text{O} \quad \text{NH}_2 \quad \text{OH} \quad \text{H}_2\text{O} \quad \text{H}^{+}
\]

The product of this reaction has a negative charge on an oxygen atom. We have put it in a circle to make it clearer, and we suggest you do the same when you draw charges: + and – signs are easily mislaid. We shall discuss this type of reaction, the way in which reactions are drawn, and what the ‘curly arrows’ in the diagram mean in Chapter 5. But for now, notice that we drew out the CO\(_2\)H as the fragment on the left because we wanted to show how the O–H bond was broken when the base attacked. We modified our diagram to suit our own purposes.

When leucine acts as a base, the amino (NH\(_2\)) group is involved. The nitrogen atom attaches itself to a proton, forming a new bond using its lone pair.

We can represent this reaction as:

\[
\text{CO}_2\text{H} \quad \text{N} \quad \text{H} \quad \text{H} \quad \text{H} \quad \text{H} \quad \text{H}_2\text{O} \quad \text{H}^{+}
\]

Notice how we drew in the lone pair this time because we wanted to show how it was involved in the reaction. The oxygen atoms of the carboxylic acid groups also have lone pairs but we didn’t draw them in because they weren’t relevant to what we were talking about. Neither did we feel it was necessary to draw CO\(_2\)H in full this time because none of the atoms or bonds in the carboxylic acid functional group was involved in the reaction.

Structural diagrams can show three-dimensional information on a two-dimensional page

Of course, all the structures we have been drawing give only an idea of the real structure of the molecules. For example, the carbon atom between the NH\(_2\) group and the CO\(_2\)H group of leucine has a tetrahedral arrangement of atoms around it, a fact which we have so far completely ignored.

We might want to emphasize this fact by drawing in the hydrogen atom we missed out at this point, as in structure 1 (in the right-hand margin). We can then show that one of the groups attached to this carbon atom comes towards us, out of the plane of the paper, and the other one goes away from us, into the paper.

There are several ways of doing this. In structure 2, the bold, wedged bond suggests a perspective view of a bond coming towards you, while the hashed bond suggests a bond fading away from you. The other two ‘normal’ bonds are in the plane of the paper.

Alternatively we could miss out the hydrogen atom and draw something a bit neater, although slightly less realistic, as in structure 3. We can assume the missing hydrogen atom is behind the plane of the paper because that is where the ‘missing’ vertex of the tetrahedron of atoms attached to the carbon atom lies. When you draw diagrams like these to indicate the three dimensional shape of the molecule, try to keep the hydrocarbon framework in the...
plane of the paper and allow functional groups and other branches to project forwards out of
the paper or backwards into it.

These conventions allow us to give an idea of the three-dimensional shape (stereochemistry) of any organic molecule—you have already seen them in use in the diagram of the structure of palytoxin at the beginning of this chapter.

Reminder

Organic structural drawings should be realistic, economical, and clear.

We gave you three guidelines to help you achieve this when you draw structures:

• Guideline 1: Draw chains of atoms as zig-zags.
• Guideline 2: Miss out the Hs attached to the carbon atoms along with the C–H bonds.
• Guideline 3: Miss out the capital Cs representing carbon atoms.

The guidelines we have given and the conventions we have illustrated in this section have grown up over decades. They are not arbitrary pronouncements by some official body but are used by organic chemists because they work! We guarantee to follow them for the rest of the book—try to follow them yourself whenever you draw an organic structure. Before you ever draw a capital C or a capital H again, ask yourself whether it’s really necessary!

Now that we have considered how to draw structures, we can return to some of the structural types that we find in organic molecules. Firstly, we’ll talk about hydrocarbon frameworks, then about functional groups.

Hydrocarbon frameworks

Carbon as an element is unique in the variety of structures it can form. It is unusual because it forms strong, stable bonds to the majority of elements in the periodic table, including itself. It is this ability to form bonds to itself that leads to the variety of organic structures that exist, and indeed to the possibility of life existing at all. Carbon may make up only 0.2% of the earth’s crust, but it certainly deserves a whole branch of chemistry all to itself.

Chains

The simplest class of hydrocarbon frameworks contains just chains of atoms. The fatty acids we met earlier have hydrocarbon frameworks made of zig-zag chains of atoms, for example. Polythene is a polymer whose hydrocarbon framework consists entirely of chains of carbon atoms. The wiggly line at each end of this structure shows that we have drawn a piece in the middle of the polythene molecule. The structure continues indefinitely beyond the wiggly lines.

At the other end of the spectrum of complexity is this antibiotic, extracted from a fungus in 1995 and aptly named linearmycin as it has a long linear chain. The chain of this antibiotic is so long that we have to wrap it round two corners just to get it on the page. We haven’t drawn whether the CH₃ and OH groups are in front of or behind the plane of the paper because, at the time of writing this book, the stereochemistry of linearmycin is unknown.
Names for carbon chains

It is often convenient to refer to a chain of carbon atoms by a name indicating its length. You have probably met some of these names before in the names of the simplest organic molecules, the alkanes. There are also commonly used abbreviations for these names: these can be very useful in both writing about chemistry and in drawing chemical structures, as we shall see shortly.

<table>
<thead>
<tr>
<th>Number of carbon atoms in chain</th>
<th>Name of group</th>
<th>Formula$^1$</th>
<th>Abbreviation</th>
<th>Name of alkane (= chain + H)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>methyl</td>
<td>–CH$_3$</td>
<td>Me</td>
<td>methane</td>
</tr>
<tr>
<td>2</td>
<td>ethyl</td>
<td>–CH$_2$CH$_3$</td>
<td>Et</td>
<td>ethane</td>
</tr>
<tr>
<td>3</td>
<td>propyl</td>
<td>–CH$_2$CH$_2$CH$_3$</td>
<td>Pr</td>
<td>propane</td>
</tr>
<tr>
<td>4</td>
<td>butyl</td>
<td>–(CH$_2$)$_3$CH$_3$</td>
<td>Bu</td>
<td>butane</td>
</tr>
<tr>
<td>5</td>
<td>pentyl</td>
<td>–(CH$_2$)$_4$CH$_3$</td>
<td>—$^\dagger$</td>
<td>pentane</td>
</tr>
<tr>
<td>6</td>
<td>hexyl</td>
<td>–(CH$_2$)$_5$CH$_3$</td>
<td>—$^\dagger$</td>
<td>hexane</td>
</tr>
<tr>
<td>7</td>
<td>heptyl</td>
<td>–(CH$_2$)$_6$CH$_3$</td>
<td>—$^\dagger$</td>
<td>heptane</td>
</tr>
<tr>
<td>8</td>
<td>octyl</td>
<td>–(CH$_2$)$_7$CH$_3$</td>
<td>—$^\dagger$</td>
<td>octane</td>
</tr>
<tr>
<td>9</td>
<td>nonyl</td>
<td>–(CH$_2$)$_8$CH$_3$</td>
<td>—$^\dagger$</td>
<td>nonane</td>
</tr>
<tr>
<td>10</td>
<td>decyl</td>
<td>–(CH$_2$)$_9$CH$_3$</td>
<td>—$^\dagger$</td>
<td>decane</td>
</tr>
</tbody>
</table>

$^1$ This representation is not recommended, except for CH$_3$. $^\dagger$ Names for longer chains are not commonly abbreviated.

Organic elements

You may notice that the abbreviations for the names of carbon chains look very much like the symbols for chemical elements: this is deliberate, and these symbols are sometimes called ‘organic elements’. They can be used in chemical structures just like element symbols. It is often convenient to use the ‘organic element’ symbols for short carbon chains for tidiness. Here are some examples. Structure 1 to the right shows how we drew the structure of the amino acid methionine on p. 20. The stick representing the methyl group attached to the sulfur atom does, however, look a little odd. Most chemists would draw methionine as structure 2, with ‘Me’ representing the CH$_3$ (methyl) group. Tetraethyllead used to be added to petrol to prevent engines ‘knocking’, until it was shown to be a health hazard. Its structure (as you might easily guess from the name) is easy to write as PbEt$_4$ or Et$_4$Pb.

Remember that these symbols (and names) can be used only for terminal chains of atoms. We couldn’t abbreviate the structure of lysine to 3, for example, because Bu represents 4 and not 5.
Before leaving carbon chains, we must mention one other very useful organic element symbol, R. R in a structure can mean anything—it’s a sort of wild card. For example, structure 6 would indicate any amino acid, if R = H it is glycine, if R = Me it is alanine… As we’ve mentioned before, and you will see later, the reactivity of organic molecules is so dependent on their functional groups that the rest of the molecule can be irrelevant. In these cases, we can choose just to call it R.

**Carbon rings**

Rings of atoms are also common in organic structures. You may have heard the famous story of Auguste Kekulé first realizing that benzene has a ring structure when he dreamed of snakes biting their own tails. You have met benzene rings in phenylalanine and aspirin. Paracetamol also has a structure based on a benzene ring.

When a benzene ring is attached to a molecule by only one of its carbon atoms (as in phenylalanine, but not paracetamol or aspirin), we can call it a ‘phenyl’ group and give it the organic element symbol Ph.

Any compound containing a benzene ring or a related (Chapter 7) ring system is known as ‘aromatic’, and another useful organic element symbol related to Ph is Ar (for ‘aryl’). While Ph always means C₆H₅, Ar can mean any substituted phenyl ring, in other words phenyl with any number of the hydrogen atoms replaced by other groups. Of course Ar = argon too but there is no confusion as there are no organic compounds of argon.
For example, while PhOH always means phenol, ArOH could mean phenol, 2,4,6-trichlorophenol (the antiseptic TCP), paracetamol, or aspirin (among many other substituted phenols). Like R, the ‘wild card’ alkyl group, Ar is a ‘wild card’ aryl group.

The compound known as muscone has only relatively recently been made in the laboratory. It is the pungent aroma that makes up the base-note of musk fragrances. Before chemists had determined its structure and devised a laboratory synthesis the only source of musk was the musk deer, now rare for this very reason. Muscone’s skeleton is a 13-membered ring of carbon atoms.

The steroid hormones have several (usually four) rings fused together. These hormones are testosterone and oestradiol, the important human male and female sex hormones.

Some ring structures are much more complicated. The potent poison strychnine is a tangle of interconnecting rings.

One of the most elegant ring structures is shown above and is known as buckminsterfullerene. It consists solely of 60 carbon atoms in rings that curve back on themselves to form a football-shaped cage. Count the number of bonds at any junction and you will see they add up to four so no hydrogens need be added. This compound is C_{60}. Note that you can’t see all the atoms as some are behind the sphere.

Rings of carbon atoms are given names starting with ‘cyclo’, followed by the name for the carbon chain with the same number of carbon atoms. Structure 1 shows chrysanthemic acid, part of the naturally occurring pesticides called pyrethrins (an example appears in Chapter 1), which contains a cyclopropane ring. Propane has three carbon atoms. Cyclopropane is a three-membered ring. Grandisol (structure 2), an insect pheromone used by male boll weevils to attract females, has a structure based on a cyclobutane ring. Butane has four carbon atoms. Cyclobutane is a four-membered ring. Cyclamate (structure 3), formerly used as an artificial sweetener, contains a cyclohexane ring. Hexane has six carbon atoms. Cyclohexane is a six-membered ring.

**Branches**

Hydrocarbon frameworks rarely consist of single rings or chains, but are often branched. Rings, chains, and branches are all combined in structures like that of the marine toxin palytoxin that we met at the beginning of the chapter, polystyrene, a polymer made of six-membered rings dangling from linear carbon chains, or of β-carotene, the compound that makes carrots orange.
Just like some short straight carbon chains, some short branched carbon chains are given names and organic element symbols. The most common is the isopropyl group. Lithium diisopropylamide (also called LDA) is a strong base commonly used in organic synthesis.

\[
\text{Lithium diisopropylamide (LDA)} \quad \text{is equivalent to LiN}^\text{i-Pr}_2
\]

Notice how the ‘propyl’ part of ‘isopropyl’ still indicates three carbon atoms; they are just joined together in a different way—in other words, as an isomer of the straight chain propyl group. Sometimes, to avoid confusion, the straight chain alkyl groups are called ‘n-alkyl’ (for example, \(n\)-Pr, \(n\)-Bu)—\(n\) for ‘normal’—to distinguish them from their branched counterparts. Iproniazid is an antidepressant drug with \(i\)-Pr in both structure and name. ‘Isopropyl’ may be abbreviated to \(i\)-Pr, \(i\)Pr, or Pr\(_i\). We shall use the first in this book, but you may see the others used elsewhere.

- **Isomers** are molecules with the same kinds and numbers of atoms joined up in different ways. \(n\)-propanol, \(n\)-PrOH, and isopropanol, \(i\)-PrOH, are isomeric alcohols. Isomers need not have the same functional groups—these compounds are all isomers of \(C_3H_8O\):

\[
\begin{align*}
\text{\(n\)-propanol} & : \text{\(C_3H_7OH\)} \\
\text{\(i\)-propanol} & : \text{\(C_3H_7OH\)}
\end{align*}
\]

The isobutyl (\(i\)-Bu) group is a \(CH_3\) group joined to an \(i\)-Pr group. It is \(i\)-PrCH\(_2\)\(_3\). Two isobutyl groups are present in the reducing agent diisobutyl aluminium hydride (DIBAL). The pain-killer ibuprofen (marketed as Nurofen\textsuperscript{®}) contains an isobutyl group. Notice how the invented name ibuprofen is a medley of ‘ibu’ (from \(i\)-Bu for isobutyl) + ‘pro’ (for propyl, the three-carbon unit shown in brown) + ‘fen’ (for the phenyl ring). We will talk about the way in which compounds are named later in this chapter.

\[
\text{Diisobutyl aluminium hydride (DIBAL)} \quad \text{is equivalent to } \text{HAI}^\text{i-Bu}_2
\]

There are two more isomers of the butyl group, both of which have common names and abbreviations. The sec-butyl group (\(s\)-butyl or \(s\)-Bu) has a methyl and an ethyl group joined to the same carbon atom. It appears in an organolithium compound, sec-butyl lithium, used to introduce lithium atoms into organic molecules.
The tert-butyl group (t-butyl or t-Bu) group has three methyl groups joined to the same carbon atom. Two t-Bu groups are found in butylated hydroxy toluene (BHT E321), an antioxidant added to some processed foods.

**Primary, secondary, and tertiary**

The prefixes sec and tert are really short for secondary and tertiary, terms that refer to the carbon atom that attaches these groups to the rest of the molecular structure.

A primary carbon atom is attached to only one other C atom, a secondary to two other C atoms, and so on. This means there are five types of carbon atom. These names for bits of hydrocarbon framework are more than just useful ways of writing or talking about chemistry. They tell us something fundamental about the molecule and we shall use them when we describe reactions.

This quick architectural tour of some of the molecular edifices built by nature and by humans serves just as an introduction to some of the hydrocarbon frameworks you will meet in the rest of this chapter and this book. Yet, fortunately for us, however complicated the hydrocarbon framework might be, it serves only as a support for the functional groups. And, by and large, a functional group in one molecule behaves in much the same way as it does in another molecule. What we now need to do, and we start in the next section, is to introduce you to some functional groups and explain why it is that their attributes are the key to understanding organic chemistry.

**Functional groups**

If you bubble ethane gas (CH₃CH₃, or EtH) through acids, bases, oxidizing agents, reducing agents—in fact almost any chemical you can think of—it will remain unchanged. Just about the only thing you can do with it is burn it. Yet ethanol (CH₃CH₂OH, or preferably EtOH—structure in the margin) not only burns, it reacts with acids, bases, and oxidizing agents.

The difference between ethanol and ethane is the functional group—the OH, or hydroxyl group. We know that these chemical properties (being able to react with acids, bases, and oxidizing agents) are properties of the hydroxyl group and not just of ethanol because other compounds containing OH groups (in other words, other alcohols) have similar properties, whatever their hydrocarbon frameworks.

Your understanding of functional groups will be the key to your understanding of organic chemistry. We shall therefore now go on to meet some of the most important functional groups. We won’t say much about the properties of each group; that will come in Chapter 5.
and later. Your task at this stage is to learn to recognize them when they appear in structures, so make sure you learn their names. The classes of compound associated with some functional groups also have names, for example compounds containing the hydroxyl group are known as alcohols. Learn these names too as they are more important than the systematic names of individual compounds. We’ve told you a few snippets of information about each group to help you to get to know something of the group’s character.

**Alkanes contain no functional groups**

The alkanes are the simplest class of organic molecules because they contain no functional groups. They are extremely unreactive and therefore rather boring as far as the organic chemist is concerned. However, their unreactivity can be a bonus, and alkanes such as pentane and hexane are often used as solvents, especially for the purification of organic compounds. Just about the only thing alkanes will do is burn—methane, propane, and butane are all used as domestic fuels, and petrol is a mixture of alkanes containing largely isooctane.

**Alkenes (sometimes called olefins) contain C=C double bonds**

It may seem strange to classify a type of bond as a functional group, but you will see later that C=C double bonds impart reactivity to an organic molecule just as functional groups consisting of, say, oxygen or nitrogen atoms do. Some of the compounds produced by plants and used by perfumers are alkenes (see Chapter 1). For example, pinene has a smell evocative of pine forests, while limonene smells of citrus fruits.

You’ve already met the orange pigment β-carotene. Eleven C=C double bonds make up most of its structure. Coloured organic compounds often contain chains or rings of C=C double bonds like this. In Chapter 7 you will find out why this is so.

**Alkynes contain C≡C triple bonds**

Just like C=C double bonds, C≡C triple bonds have a special type of reactivity associated with them, so it’s useful to call a C≡C triple bond a functional group. Alkynes are linear so we
draw them with four carbon atoms in a straight line. Alkynes are not as widespread in nature as alkenes, but one fascinating class of compounds containing C≡C triple bonds is a group of antitumour agents discovered during the 1980s. Calicheamicin is a member of this group. The high reactivity of this combination of functional groups enables calicheamicin to attack DNA and prevent cancer cells from proliferating. For the first time we have drawn a molecule in three dimensions, with two bonds crossing one another—can you see the shape?

![calicheamicin](image)

**Alcohols (R–OH) contain a hydroxyl (OH) group**

We’ve already talked about the hydroxyl group in ethanol and other alcohols. Carbohydrates are peppered with hydroxyl groups; sucrose has eight of them, for example (a more three-dimensional picture of the sucrose molecule appears in Chapter 1, p.3).

![sucrose](image)

Molecules containing hydroxyl groups are often soluble in water, and living things often attach sugar groups, containing hydroxyl groups, to otherwise insoluble organic compounds to keep them in solution in the cell. Calicheamicin, a molecule we have just mentioned, contains a string of sugars for just this reason. The liver carries out its task of detoxifying unwanted organic compounds by repeatedly hydroxylating them until they are water soluble, and they are then excreted in the bile or urine.

**Ethers (R₁–O–R₂) contain an alkoxy group (–OR)**

The name ether refers to any compound that has two alkyl groups linked through an oxygen atom. ‘Ether’ is also used as an everyday name for diethyl ether, Et₂O. You might compare this use of the word ‘ether’ with the common use of the word ‘alcohol’ to mean ethanol. Diethyl ether is a highly flammable solvent that boils at only 35°C. It used to be used as an anaesthetic. Tetrahydrofuran (THF) is another commonly used solvent and is a cyclic ether.

Brevetoxin B (overleaf) is a fascinating naturally occurring compound that was synthesized in the laboratory in 1995. It is packed with ether functional groups in ring sizes from 6 to 8.

**Amines (R–NH₂) contain the amino (NH₂) group**

We met the amino group when we were discussing the amino acids: we mentioned that it was this group that gave these compounds their basic properties. Amines often have powerful fishy smells: the smell of putrescine is particularly foul. It is formed as meat decays. Many neurologically active compounds are also amines: amphetamine is a notorious stimulant.
Nitro compounds (R–NO₂) contain the nitro group (NO₂)

The nitro group (NO₂) is sometimes incorrectly drawn with five bonds to nitrogen which you will see in Chapter 4 is impossible. Make sure you draw it correctly when you need to draw it out in detail. If you write just NO₂ you are all right!

Several nitro groups in one molecule can make it quite unstable and even explosive. Three nitro groups give the most famous explosive of all, trinitrotoluene (TNT), its kick. However, functional groups refuse to be stereotyped. Nitrazepam also contains a nitro group, but this compound is marketed as Mogadon®, the sleeping pill.

Alkyl halides (fluorides R–F, chlorides R–Cl, bromides R–Br, or iodides R–I) contain the fluoro, chloro, bromo, or iodo groups

These four functional groups have similar properties, although alkyl iodides are the most reactive and alkyl fluorides the least. Polyvinyl chloride (PVC) is one of the most widely used polymers—it has a chloro group on every other carbon atom along a linear hydrocarbon framework. Methyl iodide (MeI), on the other hand, is a dangerous carcinogen since it reacts with DNA and can cause mutations in the genetic code. These compounds are also known as haloalkanes (fluoroalkanes, chloroalkanes, bromoalkanes, or iodoalkanes).

Aldehydes (R–CHO) and ketones (R¹–CO–R²) contain the carbonyl group C=O

Aldehydes can be formed by oxidizing alcohols—in fact the liver detoxifies ethanol in the bloodstream by oxidizing it first to acetaldehyde (ethanal, CH₂CHO) (see p. 28). Acetaldehyde in the blood is the cause of hangovers. Aldehydes often have pleasant smells—2-methylundecan-1-ol is a key component of the fragrance of Chanel No. 5, and ‘raspberry ketone’ is the major component of the flavour and smell of raspberries.
Carboxylic acids (R–CO₂H) contain the carboxyl group CO₂H

As their name implies, compounds containing the carboxylic acid (CO₂H) group can react with bases, losing a proton to form carboxylate salts. Edible carboxylic acids have sharp flavours and several are found in fruits—citric, malic, and tartaric acids are found in lemons, apples, and grapes, respectively.

Esters (R¹–CO₂R²) contain a carboxyl group with an extra alkyl group (CO₂R)

Fats are esters; in fact they contain three ester groups. They are formed in the body by condensing glycerol, a compound with three hydroxyl groups, with three fatty acid molecules. Other, more volatile, esters have pleasant, fruity smells and flavours. These three are components of the flavours of bananas, rum, and apples:

Amides (R–CONH₂, R¹–CONHR₂, or R¹–CONR₂R³)

Proteins are amides: they are formed when the carboxylic acid group of one amino acid condenses with the amino group of another to form an amide linkage (also known as a peptide bond). One protein molecule can contain hundreds of amide bonds. Aspartame, the artificial sweetener marketed as NutraSweet®, on the other hand, contains just two amino acids, aspartic acid and phenylalanine, joined through one amide bond. Paracetamol is also an amide.

Nitriles or cyanides (R–CN) contain the cyano group –C≡N

Nitrile groups can be introduced into molecules by reacting potassium cyanide with alkyl halides. The organic nitrile group has quite different properties from those associated with lethal inorganic cyanide: laetrile, for example, is extracted from apricot kernels, and was once developed as an anticancer drug.

Acetyl chlorides (acid chlorides, R–COCl)

Acyl chlorides are reactive compounds used to make esters and amides. They are derivatives of carboxylic acids with the –OH replaced by –Cl, and are too reactive to be found in nature.
Acetals

Acetals are compounds with two single-bonded oxygen atoms attached to the same carbon atom. Many sugars are acetals, as is laetrile, which you have just met.

![An acetal, sucrose, and laetrile](image)

### Carbon atoms carrying functional groups can be classified by oxidation level

All functional groups are different, but some are more different than others. For example, the structures of a carboxylic acid, an ester, and an amide are all very similar: in each case the carbon atom carrying the functional group is bonded to two heteroatoms, one of the bonds being a double bond. You will see in Chapter 10 that this similarity in structure is mirrored in the reactions of these three types of compounds and in the ways in which they can be interconverted. Carboxylic acids, esters, and amides can be changed one into another by reaction with simple reagents such as water, alcohols, or amines plus appropriate catalysts. To change them into aldehydes or alcohols requires a different type of reagent, a reducing agent (a reagent which adds hydrogen atoms). We say that the carbon atoms carrying functional groups that can be interconverted without the need for reducing agents (or oxidizing agents) have the same oxidation level—in this case, we call it the ‘carboxylic acid oxidation level’.

#### The carboxylic oxidation level

- Carboxylic acids
- Esters
- Amides
- Nitriles
- Acyl chlorides

In fact, amides can quite easily be converted into nitriles just by dehydration (removal of water), so we must give nitrile carbon atoms the same oxidation level as carboxylic acids, esters, and amides. Maybe you’re beginning to see the structural similarity between these four functional groups that you could have used to assign their oxidation level? In all four cases, the carbon atom has three bonds to heteroatoms; they are at the ‘aldehyde oxidation level’. The common laboratory solvent dichloromethane CH₂Cl₂ also has two bonds to heteroatoms, so it too contains a carbon atom at the aldehyde oxidation level, as do acetals.

#### The aldehyde oxidation level

- Aldehydes
- Ketones
- Acetals
- Dichloromethane

Aldehydes and ketones contain a carbon atom with two bonds to heteroatoms; they are at the ‘aldehyde oxidation level’. The common laboratory solvent dichloromethane CH₂Cl₂ also has two bonds to heteroatoms, so it too contains a carbon atom at the aldehyde oxidation level, as do acetals.

#### The alcohol oxidation level

- Alcohols
- Ethers
- Alkyl halides

A heteroatom is an atom that is not C or H

You’ve seen that a functional group is essentially any deviation from an alkane structure, either because the molecule has fewer hydrogen atoms than an alkane (alkenes, alkynes) or because it contains a collection of atoms that are not C and not H. There is a useful term for these ‘different’ atoms: heteroatoms. A heteroatom is any atom in an organic molecule other than C or H.

Don’t confuse oxidation level with oxidation state. Oxidation level is determined by the number of heteroatoms bonded to carbon while oxidation state is determined by the number of bonds to carbon, including those to C and H. In all of these compounds, carbon has four bonds and is in oxidation state +4.

‘CFC-113’
Alcohols, ethers, and alkyl halides have a carbon atom with only one single bond to a heteroatom. We assign these the ‘alcohol oxidation level’, and they are all easily made from alcohols without oxidation or reduction.

- **The alkane oxidation level**

We must include simple alkanes, which have no bonds to heteroatoms, as an ‘alkane oxidation level’.

- **The carbon dioxide oxidation level**

The small class of compounds that have a carbon atom with four bonds to heteroatoms is related to CO₂ and best described as at the carbon dioxide oxidation level.

Alkenes and alkynes obviously don’t fit easily into these categories as they have no bonds to heteroatoms. Alkenes can be made from alcohols by dehydration without any oxidation or reduction so it seems sensible to put them in the alcohol column. Similarly, alkynes and aldehydes are related by hydration/dehydration without oxidation or reduction.

- **Summary: Important functional groups and oxidation level**

**Naming compounds**

So far, we have talked a lot about compounds by name. Many of the names we’ve used (palytoxin, muscone, brevetoxin) are simple names given to complicated molecules without regard for the actual structure or function of the molecule—these three names, for example, are all derived from the name of the organism from which the compound was first extracted.
They are known as trivial names, not because they are unimportant, but because they are used in everyday scientific conversation.

Names like this are fine for familiar compounds that are widely used and referred to by chemists, biologists, doctors, nurses, and perfumers alike. But there are over 16 million known organic compounds. They can’t all have simple names, and no-one would remember them if they did. For this reason, the International Union of Pure and Applied Chemistry (IUPAC) have developed systematic nomenclature, a set of rules that allows any compound to be given a unique name that can be deduced directly from its chemical structure. Conversely, a chemical structure can be deduced from its systematic name.

The problem with systematic names is that they tend to be grotesquely unpronounceable for anything but the most simple molecules. In everyday speech and writing, chemists therefore do tend to disregard them, and use a mixture of systematic and trivial names. Nonetheless, it’s important to know how the rules work. We shall look next at systematic nomenclature, before going on to look at the real language of chemistry.

**Systematic nomenclature**

There isn’t space here to explain all the rules for giving systematic names for compounds—they fill several desperately dull volumes, and there’s no point knowing them anyway since computers will do the naming for you. What we will do is to explain the principles underlying systematic nomenclature. You should understand these principles because they provide the basis for the names used by chemists for the vast majority of compounds that do not have their own trivial names.

Systematic names can be divided into three parts: one describes the hydrocarbon framework, one describes the functional groups, and one indicates where the functional groups are attached to the skeleton.

You have already met the names for some simple fragments of hydrocarbon framework (methyl, ethyl, propyl). Adding a hydrogen atom to these alkyl fragments and changing -yl to -ane makes the alkanes and their names. You should hardly need reminding of their structures:

### Names for the hydrocarbon framework

</tbody>
</table>
The name of a functional group can be added to the name of a hydrocarbon framework either as a suffix or as a prefix. Some examples follow. It is important to count all of the carbon atoms in the chain, even if one of them is part of a functional group: pentanenitrile is actually BuCN.

Compounds with functional groups attached to a benzene ring are named in a similar way.

**Numbers are used to locate functional groups**

Sometimes a number can be included in the name to indicate which carbon atom the functional group is attached to. None of the above list needed a number—check that you can see why not for each one. When numbers are used, the carbon atoms are counted from one end. In most cases, either of two numbers could be used (depending on which end you count from); the one chosen is always the lower of the two. Again, some examples will illustrate this point. Notice again that some functional groups are named by prefixes, some by suffixes, and that the number always goes directly before the functional group name.

One carbon atom can have as many as four functional groups: this limit is reached with tetrabromomethane, CBr₄. Here are some other examples of compounds with more than one functional group.

Again, the numbers indicate how far the functional groups are from the end of the carbon chain. Counting must always be from the same end for each functional group. Notice how we use di-, tri-, and tetra- if there is more than one of the same functional group.

With cyclic compounds, there isn’t an end to the chain, but we can use numbers to show the distance between the two groups—start from the carbon atom carrying one of the functional groups, then count round. These rules work for hydrocarbon frameworks that are
chains or rings, but many skeletons are branched. We can name these by treating the branch as though it were a functional group.

**2-amino-cyclohexanol**

**2,4,6-trinitrobenzoic acid**

**2-methylbutane**

**1,3,5-trimethyl-benzene**

**1-butylcyclopropanol**

---

**Ortho, meta, and para**

With substituted benzene rings, an alternative way of identifying the positions of the substituents is to use the terms ortho, meta, and para. Ortho compounds are 1,2-disubstituted, meta compounds are 1,3-disubstituted, and para compounds are 1,4-disubstituted. Some examples should make this clear.

**1,2-dichlorobenzene**

**3-chlorobenzoic acid**

**4-aminophenol**

The terms ortho, meta, and para are used by chemists because they’re easier to remember than numbers, and the words carry with them chemical meaning. Ortho shows that two groups are next to each other on the ring even though the atoms may not happen to be numbered 1 and 2. They are one example of the way in which chemists don’t always use systematic nomenclature but revert to more convenient ‘trivial’ terms. We consider trivial names in the next section.

**What do chemists really call compounds?**

The point of naming a compound is to be able to communicate with other chemists. Most chemists are happiest communicating chemistry by means of structural diagrams, and structural drawings are far more important than any sort of chemical nomenclature. That’s why we explained in detail how to draw structures, but only gave an outline of how to name compounds. Good diagrams are easy to understand, quick to draw, and difficult to misinterpret.

- Always give a diagram alongside a name unless it really is something very simple, such as ethanol.

But we do need to be able to communicate by speech and by writing as well. In principle we could do this by using systematic names. In practice, however, the full systematic names of anything but the simplest molecules are far too clumsy for use in everyday chemical speech. There are several alternatives, mostly based on a mixture of trivial and systematic names.

**Names for well-known and widely used simple compounds**

A few simple compounds are called by trivial names not because the systematic names are complicated, but just out of habit. We know them so well that we use their familiar names.
You may have met the compound on the right before and perhaps called it ethanoic acid, its systematic name. But in a chemical laboratory everyone would refer to this acid as acetic acid, its trivial name. The same is true for all these common substances.

Trivial names like this are often long-lasting, well-understood historical names that are less easy to confuse than their systematic counterparts. ‘Acetaldehyde’ is easier to distinguish from ‘ethanol’ than is ‘ethanal’.

Trivial names also extend to fragments of structures containing functional groups. Acetone, acetaldehyde, and acetic acid all contain the acetyl group (MeCO−, ethanoyl) abbreviated Ac and chemists often use this organic element symbol in writing AcOH for acetic acid or EtOAc for ethyl acetate. Chemists use special names for four fragments because they have mechanistic as well as structural significance. These are vinyl and allyl, phenyl and benzyl.

Giving the vinyl group a name allows chemists to use simple trivial names for compounds like vinyl chloride, the material that polymerizes to give PVC (polyvinyl chloride) but the importance of the name lies more in the difference in reactivity (Chapter 15) between the vinyl and allyl groups.

The allyl group gets its name from garlic (Allium sp.) because it makes up part of the structure of the compounds on the right responsible for the taste and smell of garlic.

Allyl and vinyl are different in that the vinyl group is attached directly to a double-bonded C=C carbon atom, while the allyl group is attached to a carbon atom adjacent to the C=C double bond. The difference is extremely important chemically: allyl compounds are typically quite reactive, while vinyl compounds are fairly unreactive.

For some reason, the allyl and vinyl groups have never acquired organic element symbols, but the benzyl group has and it is Bn. It is again important not to confuse the benzyl group with the phenyl group: the phenyl group is joined through a carbon atom in the ring, while the benzyl group is joined through a carbon atom attached to the ring. Phenyl compounds are typically unreactive but benzyl compounds are often reactive. Phenyl is like vinyl, and benzyl is like allyl. We shall review all the organic element symbols you have met at the end of the chapter.
Names for more complicated but still well-known molecules

Complicated molecules that have been isolated from natural sources are always given trivial names because in these cases the systematic names really are impossible! Strychnine is a famous poison featured in many detective stories and a molecule with a beautiful structure. All chemists refer to it as strychnine as the systematic name is virtually unpronounceable. Two groups of experts at IUPAC and Chemical Abstracts also have different ideas on the systematic name for strychnine. Others like this are penicillin, DNA, and folic acid.

But the champion is vitamin B_{12}, a complicated cobalt complex with a three-dimensional structure of great intricacy. No chemist would learn this structure but would look it up in an advanced textbook of organic chemistry. You will find it in such books in the index under vitamin B_{12} and not under its systematic name. We do not even know what its systematic name might be and we are not very interested.
Even fairly simple but important molecules, the amino acids for example, which have systematic names that are relatively easy to understand, are normally referred to by their trivial names, which are, with a bit of practice, easy to remember and hard to muddle up. They are given in full in Chapter 23.

A very flexible way of getting new, simple names for compounds can be to combine a bit of systematic nomenclature with trivial nomenclature. Alanine is a simple amino acid that occurs in proteins. Add a phenyl group and you have phenylalanine, which is a more complex amino acid also in proteins. Toluene, the common name for methylbenzene, can be combined (both chemically and in making names for compounds!) with three nitro groups to give the famous explosive trinitrotoluene or TNT.

Compounds named as acronyms

Some compounds are referred to by acronyms, shortened versions of either their systematic or their trivial name. We just saw TNT as an abbreviation for TriNitroToluene but the more common use for acronyms is to define solvents and reagents in use all the time. Later in the book you will meet these solvents:

The following reagents are usually referred to by acronym and their functions will be introduced in other chapters so you do not need to learn them now. You may notice that some acronyms refer to trivial and some to systematic names.

Compounds for which chemists use systematic names

You may be surprised to hear that practising organic chemists use systematic names at all in view of what we have just described, but they do! Systematic names really begin with derivatives of
pentane ($C_{5}H_{12}$) since the prefix *pent-* means five, whereas *but-* does not mean four. Chemists refer to simple derivatives of open-chain and cyclic compounds with 5 to about 20 carbon atoms by their systematic names, providing that there is no common name in use. Here are some examples.

These names contain a syllable that tells you the framework size: *penta-* for $C_{5}$, *octa-* for $C_{8}$, *nona* for $C_{9}$, undeca-* for $C_{11}$, and dodeca-* for $C_{12}$. These names are easily worked out from the structures and, what is more important, you get a clear idea of the structure from the name. One of them might make you stop and think a bit (which one?), but the others are clear even when heard without a diagram to look at.

**Complicated molecules with no trivial names**

When chemists make complex new compounds in the laboratory, they publish the method for making them in a chemical journal, giving their full systematic names in the experimental account, however long and clumsy those names may be. But in the text of the paper, and while talking in the laboratory about the compounds they have made, they will just call them ‘the amine’ or ‘the alkene’. Everyone knows which amine or alkene is meant because at some point they remember seeing a chemical structure of the compound. This is the best strategy for talking about almost any molecule: draw a structure, then give the compound a ‘tag’ name like ‘the amine’ or ‘the acid’. In written chemistry it’s often easiest to give every chemical structure a ‘tag’ number as well. To illustrate what we mean, let’s talk about a recent drug synthesis.

This potential anti-obesity drug 1, which might overcome insulin resistance in diabetics, was recently made at Abbott laboratories from a simpler intermediate 4. In the published work the drug is called ‘a selective DGAT-1 inhibitor’ but that doesn’t mean much to us. In the text of the paper they refer to it by its compound number 1. How much more sensible than using its systematic name: *trans-*(1$R$,2$R$)-2-(*4’-(3-phenylureido)biphenylcarbonyl) cyclopentanecarboxylic acid. The simpler intermediate they call ‘the ketoacid 4’ or ‘the aryl bromide 4’ or ‘the free acid 4’ depending on what aspect of its structure they want to emphasize. Notice that in both cases a clear diagram of the structure appears with its number.

**How should you name compounds?**

So what should you call a compound? It really depends on circumstances, but you won’t go far wrong if you follow the example of this book. We shall use the names for compounds
that real chemists use. There’s no need to learn all the commonly used names for compounds now, but you should log them in your memory as you come across them. Never allow yourself to pass a compound name by unless you are sure you know what chemical structure it refers to.

### Our advice on chemical names—six points in order of importance

- Draw a structure first and worry about the name afterwards.
- Learn the names of the functional groups (ester, nitrile, etc.).
- Learn and use the names of a few simple compounds used by all chemists.
- In speech, refer to compounds as ‘that acid’ (or whatever) while pointing to a diagram.
- Grasp the principles of systematic (IUPAC) nomenclature and use it for compounds of medium size.
- Keep a notebook to record acronyms, trivial names, structures, etc. that you might need later.

We’ve met a great many molecules in this chapter. Most of them were just there to illustrate points so don’t learn their structures! Instead, learn to recognize the names of the functional groups they contain. However, there were 10 names for simple compounds and three for common solvents that we advised you to learn. Cover up the right-hand part of each column and draw the structures for these 14 compounds.

<table>
<thead>
<tr>
<th>Important structures to learn</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>acetone</td>
<td>toluene</td>
</tr>
<tr>
<td>ether or diethyl-ether</td>
<td>pyridine</td>

</tr>
<tr>
<td>benzene</td>
<td>DMF, Me₂NCHO, or dimethylformamide</td>
</tr>
<tr>
<td>ethyl acetate or EtOAc</td>
<td>DMSO</td>
</tr>
</tbody>
</table>

That’s all we’ll say on the subject of nomenclature—you’ll find that as you practise using these names and start hearing other people referring to compounds by name you’ll soon pick up the most important ones. But, to reiterate, make sure you never pass a compound name by without being absolutely sure what it refers to—draw a structure to check.
To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at http://www.oxfordtextbooks.co.uk/orc/clayden2e/
Determining organic structures

Introduction

Organic structures can be determined accurately and quickly by spectroscopy

Having urged you, in the last chapter, to draw structures realistically, we now need to answer the question: what is realistic? How do we know what structures molecules actually have? Make no mistake about this important point: we really do know what shape molecules have. You wouldn’t be far wrong if you said that the single most important development in organic chemistry in modern times is just this certainty, as well as the speed with which we can be certain. What has caused this revolution can be stated in a word—spectroscopy.

<table>
<thead>

</tr>
</tbody>
</table>

Structure of the chapter

We shall first consider structure determination as a whole and then introduce three different methods:

- mass spectrometry (to determine mass of the molecule and atomic composition)
- nuclear magnetic resonance (NMR) spectroscopy (to determine symmetry, branching, and connectivity in the molecule)
- infrared spectroscopy (to determine the functional groups in the molecule).
Of these, NMR is more important than all the rest put together and so we shall return to it in more detail in Chapter 13. Then in Chapter 18, after we’ve discussed a wider range of molecules, there will be a review chapter to bring the ideas together and show you how unknown structures are really determined.

**X-ray is the final appeal**

In Chapter 2 we suggested you draw saturated carbon chains as zig-zags and not in straight lines with 90° or 180° bond angles. This is because we know they are zig-zags. The X-ray crystal structure of the ‘straight’ chain diacid, hexanedioc acid, is shown below. You can clearly see the zig-zag chain, the planar carboxylic acid groups, and even the hydrogen atoms coming towards you and going away from you. It obviously makes sense to draw this molecule realistically, as in the second drawing.

![Hexanedioc acid](image1.png)

X-ray crystal structures are determined by allowing a sample of a crystalline compound to diffract X-rays. From the resulting diffraction pattern, it is possible to deduce the precise spatial arrangement of the atoms in the molecule—except, usually, the hydrogen atoms, which are too light to diffract the X-rays and whose position must be inferred from the rest of the structure. This is one question that X-ray answers better than any other method: what shape does a molecule have? Another important problem it can solve is the structure of an important new unknown compound. There are subterranean bacteria, for example, that use methane as an energy source. It is amazing that bacteria manage to convert methane into anything useful, and, of course, chemists really wanted to know how they did it. In 1979 it was found that the bacteria use a coenzyme, given the trivial name ‘methoxatin’, to oxidize methane to methanol. Methoxatin was a new compound with an unknown structure and could be obtained in only very small amounts. It proved exceptionally difficult to solve the structure by NMR but eventually methoxatin was found by X-ray crystallography to be a polycyclic tricarboxylic acid.

---

**Coenzymes** are biochemical reagents that work hand-in-hand with enzymes to catalyse reactions.

**The trivial name ‘methoxatin’ has a systematic alternative:** 4,5-dihydro-4,5-dioxo-1H-pyrrolo[2,3-f]quinoline-2,7,9-tricarboxylic acid. Both are valid names. There are no prizes for guessing which one is used more often.
X-ray crystallography has its limitations

If X-ray crystallography is so powerful, why do we bother with other methods? There are two reasons:

- X-ray crystallography works by the scattering of X-rays from electrons and requires crystalline solids. If an organic compound is a liquid or is a solid but does not form good crystals, its structure cannot be determined in this way.
- X-ray crystallography is a science in its own right, requiring specialized skills, and a structure determination can take a long time. Modern methods have reduced this time to a matter of hours or less, but nonetheless by contrast a modern NMR machine with a robot attachment can run more than 100 spectra overnight. We normally use NMR routinely and reserve X-rays for difficult unknown structures and for determining the detailed shape of important molecules.

X-ray crystallography is not infallible!

Because it cannot usually ‘see’ H atoms, it is important to appreciate that X-ray crystallography is not infallible: it can still get things wrong. A famous example is the antibiotic diazonamide A, which from 1991 (when it was isolated from a marine organism) until 2001 (when the error was realized) was thought to have the structure shown on the right. It has the same mass as the real structure on the left, and X-ray crystallography was unable to tell the O and the N apart. Only when the compound was synthesized did the error become apparent, and the fact that the correct structure was indeed that on the left was confirmed by the fact that synthetic material of this structure made in 2002 was identical with the natural product.

Outline of structure determination by spectroscopy

Put yourself in these situations, regularly encountered by professional chemists:

- You notice an unexpected product from a chemical reaction.
- You discover a previously unknown compound in a plant extract.
• You detect a suspected food contaminant and need to know what it is.
• You are routinely checking purity during the manufacture of a drug.

In all cases, except perhaps the second, you would need a quick and reliable answer. Suppose you are trying to identify the heart drug propranolol. You would first want to know the molecular weight and atomic composition, and these would come from a mass spectrum: propranolol has a molecular weight (relative molecular mass) of 259 and the composition C\textsubscript{16}H\textsubscript{21}NO\textsubscript{2}. Next you would need the carbon skeleton—this would come from NMR, which would reveal the three fragments shown below.

\[ \text{propranolol} \quad \text{C}_{16}\text{H}_{21}\text{NO}_2 \]

There are many ways in which the fragments seen by NMR could be joined together and at this stage you would have no idea whether the oxygen atoms were present as OH groups or as ethers, whether the nitrogen would be an amine or not, and whether Y and Z might or might not be the same atom, say N. More information comes from the infrared spectrum, which highlights the functional groups, and which would show that there is an OH and an NH in the molecule but not other functional groups such as CN or NO\textsubscript{2}. This still leaves a variety of possible structures, and these could finally be distinguished by the details revealed by \textsuperscript{1}H NMR. We will deal with \textsuperscript{1}H NMR only briefly in this chapter because it is more complicated than \textsuperscript{13}C NMR, but we will return to it in Chapter 13.

Now we must go through each of these methods and see how they give us information about the propranolol molecule.

**What each spectroscopic method tells us**

**Mass spectrometry**

**Mass spectrometry weighs the molecule**

It’s not easy to weigh a neutral molecule, and a mass spectrometer works by measuring the mass of a charged ion instead: the charge makes the molecule controllable by an electric field. A mass spectrometer therefore has three basic components:

• something to volatilize and ionize the molecule into a beam of charged particles
• something to focus the beam so that particles of the same mass:charge ratio are separated from all others and
• something to detect the particles.

All spectrometers in common use operate in a high vacuum and use one of several methods to convert neutral molecules into cations, the most common being electron impact, chemical ionization, and electrospray.
Mass spectrometry by electron impact

In electron impact (EI) mass spectrometry the molecule is bombarded with highly energetic electrons that knock a weakly bound electron out of the molecule. If you think this is strange, think of throwing bricks at a brick wall: the bricks can’t stick to the wall but can knock loose bricks off the top of the wall. Losing a single electron leaves behind an unpaired electron and a positive charge. The electron that is lost will be one of relatively high energy (the bricks come from the top of the wall), and typically one not involved in bonding, for example an electron from a lone pair.

Thus ammonia gives $\text{NH}_3^+$ and a ketone gives $\text{R}_2\text{C}=\text{O}^+$. These unstable species are known as **radical cations**, and being charged they are accelerated by an electric field and focused onto the detector, which detects the mass of the ion by how far its path has been deflected by the electric field. It only takes about 20 μs for the radical cations to reach the detector, but sometimes they fragment before they get there, in which case other ions will also be detected. These fragments will always have a lower mass than the ‘parent’ molecular ion, so in a typical mass spectrum we are most interested in the heaviest ion we can see.

A typical EI mass spectrum looks like this:

**Radical cations**

Most molecules have all their electrons paired; **radicals** have unpaired electrons. Molecules that carry a negative charge are **anions**; molecules with a positive charge are **cations**. Radical cations and radical anions are simply species that are both charged and have an unpaired electron.
This compound was identified as a pheromone deposited by worker bees when feeding as a marker to deter their colleagues from visiting the same, now depleted, nectar source. Only minute quantities are available for analysis of course, but that doesn’t matter: mass spectrometry is successful even on a microgram scale. The spectrum you see here indicates that the molecule has a mass of 114 because that is the highest mass observed in the spectrum: the molecule is in fact the volatile ketone heptan-2-one.

**Mass spectrometry by chemical ionization, electrospay, or other methods**

A problem with EI mass spectrometry is that, for fragile molecules, the energy of the bombarding electron can be sufficient to cause it to fragment completely, losing all trace of the molecular ion. Some useful information can be gained from fragmentation patterns, but in general it is more useful to aim to weigh the molecule all in one piece. This can be achieved using any of a number of other techniques, of which the most common are chemical ionization (CI) and electrospay (ES).

Chemical ionization is achieved by mixing a gas such as ammonia with the substrate in the spectrometer. Bombardment of NH₃ with electrons leads to formation of some NH₄⁺ by proton transfer, and reaction of this ion with the substrate makes a charged complex, which can be accelerated by the electric field. The masses observed by chemical ionization spectroscopy carried out in this way are usually M + 1 or M + 18 (the mass of NH₄⁺) relative to the mass of the substrate. With electrospray mass spectroscopy, an aerosol of the substrate is ionized, and ionization in the presence of sodium ions means that masses of M + 1 and M + 23 are often seen, or, if the ionization forms anions, M – 1.

This is the electrospray mass spectrum of heptan-2-one. Notice how a single molecular ion is clearly visible this time, but that it has a mass of 137, which is 23 more than the mass of 114 (in other words, this is the mass of M + Na⁺).

**Mass spectrometry detects isotopes**

Most elements can exist as more than one isotope. Usually, one isotope accounts for the vast majority (perhaps >99%) of the atoms of an element. But for some elements, atoms of several isotopes make up a significant proportion of the total in a sample. Chlorine, for example, is
normally a 3:1 mixture of $^{35}\text{Cl}$ and $^{37}\text{Cl}$ (hence the averaged relative atomic mass of 35.5 for chlorine), while bromine is an almost 1:1 mixture of $^{79}\text{Br}$ and $^{81}\text{Br}$ (hence the average mass of 80 for bromine). Because mass spectrometry weighs individual molecules, there is no averaging: instead it detects the true weight of each molecule, whatever isotope it contains.

For example, the molecular ion in the EI mass spectrum of this aryl bromide has two peaks at 186 and 188 of roughly equal intensity. Having two molecular ions of equal intensity separated by 2 mass units is indicative of bromine in a molecule.

The mass spectrum of a chlorine-containing molecule is likewise easy to identify from two peaks separated by two mass units, but this time in a ratio of 3:1, arising from the 3:1 isotopic ratio of $^{35}\text{Cl}$ and $^{37}\text{Cl}$.

What happens with more than one Br or Cl? Here’s an example: the painkiller diclofenac. This spectrum was obtained from commercial tablets, which contain the potassium salt of the active ingredient (it becomes protonated in the acidic environment of the stomach).

The ES spectrum shows the mass of the carboxylate anion as three peaks, at 294, 296, and 298. The relative size of the peaks can be worked out from the 75% probability that each Cl atom will be $^{35}\text{Cl}$ and the 25% probability it will be $^{37}\text{Cl}$. The ratios are therefore $\frac{3}{4} \times \frac{3}{4} : 2 \times \frac{1}{4} \times \frac{1}{4} : \frac{1}{4} \times \frac{1}{4}$ or 9:6:1.
Carbon has a minor but important isotope $^{13}$C

The minor isotopes of many elements that appear at below the 1% level are not usually important, but one we cannot ignore is the 1.1% of $^{13}$C present in ordinary carbon, of which the main isotope is of course $^{12}$C. Another isotope, $^{14}$C, is radioactive and used in carbon dating, but its natural abundance is minute. The stable isotope $^{13}$C is not radioactive, but it is NMR active, as we shall soon see. If you look back at all the mass spectra illustrated so far in this chapter, you will see a small peak one mass unit higher than each peak: these are peaks arising from molecules containing $^{13}$C instead of $^{12}$C. The exact height of these peaks is useful as an indication of the number of carbon atoms in the molecule. Each carbon has a 1.1% chance of being $^{13}$C rather than $^{12}$C, so the more C atoms there are the bigger this chance becomes. If there are $n$ carbon atoms in a molecular ion, then the ratio of $M^+$ to $[M + 1]^+$ is 100:$(1.1 \times n)$.

Look at the spectrum below: it’s the fuel additive Topanol 354, whose structure and molecular formula are shown. With 15 carbons, there’s a 16.5% chance there will be one $^{13}$C atom in the molecule, and you can clearly see the sizeable $M^+$ peak at 237. We can ignore the possibility of having two $^{13}$C atoms as the probability is so small.

Atomic composition can be determined by high-resolution mass spectrometry

Ordinary mass spectra tell us the molecular weight (MW) of the molecule: we could easily see, for example, that the bee pheromone on p. 48 had MW 114 even without knowing its structure. When we revealed it was $C_7H_{14}O$, we had to use other information to infer this, because 114 could also be many other things, such as $C_8H_{18}$ or $C_6H_{10}O_2$ or $C_6H_{14}N_2$. These different atomic compositions for the same molecular weight can nonetheless be distinguished if we know the exact molecular weight, since individual isotopes have non-integral masses (except $^{12}$C by definition). The table below gives these masses to five decimal places, which is the sort of accuracy you need for meaningful results. Such accurate mass measurements are obtained by a technique called high-resolution mass spectrometry.

H, N, O, S, P, F, and I have only very small amounts of isotopes other than $^{1}$H, $^{14}$N, $^{16}$O, $^{31}$P, $^{29}$Si, and $^{127}$I. The real oddity though is tin, which exists as a mixture of 10 different stable isotopes, the major ones being $^{111}$Sn (15%), $^{115}$Sn (8%), $^{116}$Sn (24%), $^{119}$Sn (9%), $^{120}$Sn (33%), $^{122}$Sn (5%), and $^{124}$Sn (6%). In reality the precise ratio of isotopes for any element varies according to its source, a fact which can supply useful forensic information.

For the bee pheromone on p. 48, the accurate mass turns out to be 114.1039. The table below compares possible atomic compositions for an approximate MW 114, and the result is conclusive. The exact masses to three places of decimals fit the observed exact mass only for the composition $C_7H_{14}O$. You may not think the fit is very good when you look at the two numbers, but notice the difference in the error expressed as parts per million. One answer stands out from the rest. Note that even two places of decimals would be enough to distinguish these four compositions.

In the rest of the book, whenever we state that a molecule has a certain atomic composition you can assume that it has been determined by high-resolution mass spectrometry on the molecular ion.

One thing you may have noticed in the table above is that there are no entries with just one nitrogen atom. Two nitrogen atoms, yes; one nitrogen no! This is because any complete molecule with C, H, O, S, and just one nitrogen in it has an odd molecular weight. This is because C, O, S, and N all have even atomic weights—only H has an odd atomic weight. Nitrogen is the only element from C, O, S, and N that can form an odd number of bonds (3). Molecules with one nitrogen atom must have an odd number of hydrogen atoms and hence an odd molecular weight.

Quick nitrogen count (for molecules containing any of the elements C, H, N, O, and S)

Molecules with an odd molecular weight must have an odd number of nitrogen atoms. Molecules with even molecular weight must have an even number of nitrogen atoms or none at all.
Nuclear magnetic resonance

What does it do?

Nuclear magnetic resonance (NMR) allows us to detect atomic nuclei and say what sort of environment they are in within the molecule. In a molecule such as propanol, the hydrogen atom of the hydroxyl group is clearly different from the hydrogen atoms of its carbon skeleton—it can be displaced by sodium metal, for example. NMR (actually $^1\text{H}$, or proton, NMR) can easily distinguish between these two sorts of hydrogens by detecting the environment the hydrogen’s nucleus finds itself in. Moreover, it can also distinguish between all the other different sorts of hydrogen atoms present. Likewise, carbon (more precisely $^{13}\text{C}$) NMR can easily distinguish between the three different carbon atoms. NMR is extremely versatile: it can even scan living human brains (see picture) but the principle is still the same: being able to detect nuclei (and hence atoms) in different environments.

NMR uses a strong magnetic field

Imagine for a moment that we were able to ‘switch off’ the earth’s magnetic field. Navigation would be made much harder since all compasses would be useless, with their needles pointing randomly in any direction. However, as soon as we switched the magnetic field back on, they would all point north—their lowest energy state. Now if we wanted to force a needle to point south we would have to use up energy and, of course, as soon as we let go, the needle would return to its lowest energy state, pointing north.

In a similar way, some atomic nuclei act like tiny compass needles when placed in a magnetic field and have different energy levels according to the direction in which they are ‘pointing’. (We will explain how a nucleus can ‘point’ somewhere in a moment.) A real compass needle can rotate through 360° and have an essentially infinite number of different energy levels, all higher in energy than the ‘ground state’ (pointing north). Fortunately, things are simpler with an atomic nucleus: its energy levels are quantized, just like the energy levels of an electron, which you will meet in the next chapter, and it can adopt only certain specific energy levels. This is like a compass which points, say, only north or south, or maybe only north, south, east, or west, and nothing in between. Just as a compass needle has to be made of a magnetic material to feel the effect of the earth’s magnetism, so it is that only certain nuclei are ‘magnetic’. Many (including ‘normal’ carbon-12, $^{12}\text{C}$) do not interact with a magnetic field at all and cannot be observed in an NMR machine. But, importantly for us in this chapter, the minor carbon isotope $^{13}\text{C}$ does display magnetic properties, as does $^1\text{H}$, the most abundant atomic nucleus on earth. When a $^{13}\text{C}$ or $^1\text{H}$ atom finds itself in a magnetic field, it has two available energy states: it can either align itself with the field (‘north’ you could say), which would be the lowest energy state, or against the field (‘south’), which is higher in energy.
The property of a nucleus that allows magnetic interactions, i.e. the property possessed by $^{13}$C and $^1$H but not by $^{12}$C, is spin. If you conceive of a $^{13}$C and $^1$H nucleus spinning, you can see how the nucleus can point in one direction—it is the axis of the spin that is aligned with or against the field.

Let’s return to the compass for a moment. If you want to move a compass needle away from pointing north, you have to push it—and expend energy as you do so. If you put the compass next to a bar magnet, the attraction towards the magnet is much greater than the attraction towards the north pole, and the needle now points at the magnet. You also have to push much harder if you want to move the needle. Exactly how hard it is to turn the compass needle depends on how strong the magnetic field is and also on how well the needle is magnetized—if it is only weakly magnetized, it is much easier to turn it round and if it isn’t magnetized at all, it is free to rotate.

Likewise, for a nucleus in a magnetic field, the difference in energy between the nuclear spin aligned with and against the applied field depends on:

- how strong the magnetic field is, and
- the magnetic properties of the nucleus itself.

The stronger the magnetic field, the greater the energy difference between the two alignments of the nucleus. Now there is an unfortunate thing about NMR: the energy difference between the nuclear spin being aligned with the magnetic field and against it is really very small—so small that we need a very, very strong magnetic field to see any difference at all.

**NMR also uses radio waves**

A $^1$H or $^{13}$C nucleus in a magnetic field can have two energy levels, and energy is needed to flip the nucleus from the more stable state to the less stable state. But since the amount of energy needed is so small, it can be provided by low-energy electromagnetic radiation of radio-wave frequency. Radio waves flip the nucleus from the lower energy state to the higher state. Turn off the radio pulse and the nucleus returns to the lower energy state. When it does so, the energy comes out again, and this (a tiny pulse of radio frequency electromagnetic radiation) is what we detect.

We can now sum up how an NMR machine works.

1. The sample of the unknown compound is dissolved in a suitable solvent, placed in a narrow tube, and put inside a very strong electromagnet. To even out imperfections in
the sample, the tube is spun very fast by a stream of air. Inside the magnetic field, any atomic nuclei with a nuclear spin now possess different energy levels, the exact number of different energy levels depending on the value of the nuclear spin. For $^1$H and $^{13}$C NMR there are two energy levels.

2. The sample is irradiated with a short pulse of radiofrequency energy. This disturbs the equilibrium balance between the two energy levels: some nuclei absorb the energy and are promoted to a higher energy level.

3. When the pulse finishes, the radiation given out as the nuclei fall back down to the lower energy level is detected using what is basically a sophisticated radio receiver.

4. After lots of computation, the results are displayed in the form of intensity (i.e. number of absorptions) against frequency. Here is an example, which we shall return to in more detail later:

![Graph showing absorption of radiation by $^{13}$C nuclei](image)

Why do chemically distinct nuclei absorb energy at different frequencies?

In the spectrum you see above, each peak represents a different kind of carbon atom: each one absorbs energy (or resonates—hence the term ‘nuclear magnetic resonance’) at a different frequency. But why should carbon atoms be ‘different’? We have told you two factors that affect the energy difference (and therefore the frequency)—the magnetic field strength and what sort of nucleus is being studied. So you might expect all $^{13}$C nuclei to resonate at one particular frequency and all protons ($^1$H) to resonate at one (different) frequency. But they don’t.

The variation in frequency for different carbon atoms must mean that the energy jump from ‘nucleus-aligned-with’ to ‘nucleus-aligned-against’ the applied magnetic field must be different for each type of carbon atom. The reason is that the $^{13}$C nuclei in question experience a magnetic field that is not quite the same as the magnetic field that we apply. Each nucleus is surrounded by electrons, and in a magnetic field these will set up a tiny electric current. This current will set up its own magnetic field (rather like the magnetic field set up by the electrons of an electric current moving through a coil of wire or solenoid), which will oppose the magnetic field that we apply. The electrons are said to shield the nucleus from the external magnetic field. If the electron distribution varies from $^{13}$C atom to $^{12}$C atom, so does the local magnetic field experienced by its nucleus, and so does the corresponding resonating frequency.
Changes in the distribution of electrons around a nucleus affect:

- the local magnetic field that the nucleus experiences
- the frequency at which the nucleus resonates
- the chemistry of the molecule at that atom

This variation in frequency is known as the chemical shift. Its symbol is $\delta$.

As an example, consider ethanol (right). The red carbon attached to the OH group will have a smaller share of the electrons around it compared to the green carbon since the oxygen atom is more electronegative and pulls electrons towards it, away from the red carbon atom.

The magnetic field that the red carbon nucleus feels will therefore be slightly greater than that felt by the green carbon, which has a greater share of the electrons, since the red carbon is less shielded from the applied external magnetic field—in other words it is deshielded. Since the carbon attached to the oxygen feels a stronger magnetic field (it is more ‘exposed’ to the field as it has lost some of its electronic shielding) there will be a greater energy difference between the two alignments of its nucleus. The greater the energy difference, the higher the resonant frequency (energy is proportional to frequency). So for ethanol we would expect the red carbon with the OH group attached to resonate at a higher frequency than the green carbon, and indeed this is exactly what the $^{13}$C NMR spectrum shows.

The chemical shift scale

When you look at a real NMR spectrum you will see that the scale does not appear to be in magnetic field units, nor in frequency, nor yet even energy, units, but in ‘parts per million’ (ppm). There is a very good reason for this. The exact frequency at which the nucleus resonates depends on the external applied magnetic field. This means that if the sample is run on a machine with a different magnetic field, it will resonate at a different frequency. It would make life very difficult if we couldn’t say exactly where our signal was, so we say how far it is from some reference sample, as a fraction of the operating frequency of the machine. We know that all protons resonate at approximately the same frequency in a given magnetic field and that the exact frequency depends on what sort of chemical environment it is in, which in turn depends on its electrons. This approximate frequency is the operating frequency of the machine and simply depends on the strength of the magnet—the stronger the magnet, the larger the operating frequency. The precise value of the operating frequency is simply the frequency at which a standard reference sample resonates. In everyday use, rather than actually referring to the strength of the magnet in tesla, chemists usually just refer to its operating frequency. A 9.4 T NMR machine is referred to as a 400 MHz spectrometer since that is the frequency in this strength field at which the protons in the reference sample resonate; other nuclei, for example $^{13}$C, would resonate at a different frequency, but the strength is arbitrarily quoted in terms of the proton operating frequency.
The reference sample—tetramethylsilane, TMS

The compound we use as a reference sample is usually tetramethylsilane, TMS. This is silane (SiH$_4$) with each of the hydrogen atoms replaced by methyl groups to give Si(CH$_3$)$_4$. The four carbon atoms attached to silicon are all equivalent and, because silicon is more electropositive than carbon, they are fairly electron-rich (or shielded), which means they resonate at a frequency a little less than that of most organic compounds. This is useful because it means our reference sample is not bang in the middle of our spectrum!

The chemical shift, $\delta$, in parts per million (ppm) of a given nucleus in our sample is defined in terms of the resonance frequency as:

$$\delta = \frac{\text{frequency (Hz)} - \text{frequency TMS (Hz)}}{\text{frequency TMS (MHz)}}$$

No matter what the operating frequency (i.e. strength of the magnet) of the NMR machine, the signals in a given sample (e.g. ethanol) will always occur at the same chemical shifts. In ethanol the (red) carbon attached to the OH resonates at 57.8 ppm whilst the (green) carbon of the methyl group resonates at 18.2 ppm. Notice that by definition TMS itself resonates at 0 ppm. The carbon nuclei in most organic compounds resonate at greater chemical shifts, normally between 0 and 200 ppm.

Now, let’s return to the sample spectrum you saw on p. 54 and which is reproduced below, and you can see the features we have discussed. This is a 100 MHz spectrum; the horizontal axis is actually frequency but is usually quoted in ppm of the field of the magnet, so each unit is one ppm of 100 MHz, that is, 100 Hz. We can tell immediately from the three peaks at 176.8, 66.0, and 19.9 ppm that there are three different types of carbon atom in the molecule.

### Regions of the $^{13}$C NMR spectrum

But we can do better than this: we can also work out what sort of chemical environment the carbon atoms are in. All $^{13}$C spectra can be divided into four major regions: saturated carbon atoms (0–50 ppm), saturated carbon atoms next to oxygen (50–100 ppm), unsaturated carbon atoms (100–150 ppm), and unsaturated carbon atoms next to oxygen, i.e. C=O groups (150 to about 200 ppm).
The spectrum you just saw is in fact that of lactic acid (2-hydroxypropanoic acid). When you turned the last page, you made some lactic acid from glucose in the muscles of your arm—it is the breakdown product from glucose when you do anaerobic exercise. Each of lactic acid’s carbon atoms gives a peak in a different region of the spectrum.

But hang on one moment, you may say—don’t we only see signals for carbon-13 nuclei and not carbon-12, which make up most of the carbon atoms in any normal sample of lactic acid? The answer is yes, and indeed only about 1.1% (the natural abundance of 13C) of the C atoms in any sample are ‘visible’ by 13C NMR. But since those 13C atoms will be distributed more or less randomly through the sample, this fact does not affect any of the arguments about the appearance of the spectrum. What it does mean, however, is that 13C NMR is not as sensitive as 1H NMR, for example, where essentially all of the H atoms in the sample will be ‘visible’.

**Different ways of describing chemical shift**

The chemical shift scale runs to the left from zero (where TMS resonates), i.e. backwards from the usual style. Chemical shift values around zero are obviously small but are confusingly called ‘high field’ because this is the high magnetic field end of the scale. We suggest you say ‘large’ or ‘small’ chemical shift and ‘large’ or ‘small’ δ, but ‘high’ or ‘low’ field to avoid confusion. Alternatively, use ‘upfield’ for high field (small δ) and ‘downfield’ for low field (large δ).

One helpful description we have already used is shielding. Each carbon nucleus is surrounded by electrons that shield the nucleus from the applied field. Simple saturated carbon nuclei are the most shielded: they have small chemical shifts (0–50 ppm) and resonate at high field. One electronegative oxygen atom moves the chemical shift downfield into the 50–100 ppm region. The nucleus has become deshielded. Unsaturated carbon atoms experience even less shielding (100–150 ppm) because of the way in which electrons are distributed around the nucleus. If they are also bonded to oxygen (the most common unsaturated carbons bonded to oxygen are those of carbonyl groups), then the nucleus is even more deshielded and moves to the largest chemical shifts around 200 ppm. The next diagram summarizes these different ways of talking about NMR spectra.

**A guided tour of the 13C NMR spectra of some simple molecules**

So, on to some real 13C NMR spectra. Our very first compound, hexanedioic acid, has the simple NMR spectrum shown here. The first question is: why only three peaks for six carbon atoms? Because of the symmetry of the molecule, the two carboxylic acids are identical and give one peak at 174.2 ppm. By the same token C2 and C5 are identical, and C3 and C4 are identical. These are all in the saturated region 0–50 ppm but the carbons next to the electron-withdrawing CO₂H group will be more deshielded than the others. So we assign C2/C5 to the peak at 33.2 ppm and C3/C4 to 24.0 ppm.
Heptan-2-one is the bee pheromone mentioned on p. 48. It has no symmetry so all its seven carbon atoms are different. The carbonyl group is easy to identify (208.8 ppm) but the rest are more difficult. The two carbon atoms next to the carbonyl group come at lowest field, while C7 is at highest field (13.9 ppm). It is important that there is the right number of signals at about the right chemical shift. If that is so, we are not worried if we cannot assign each frequency to a precise carbon atom (such as atoms 4, 5, and 6, for example). As we said before, don’t be concerned with the intensities of the peaks.

You met BHT on p. 8: its formula is C15H24O and the first surprise in its NMR spectrum is that there are only seven signals for the 15 carbon atoms. There is obviously a lot of symmetry; in fact the molecule has a plane of symmetry vertically as it is drawn here, and the coloured blobs indicate pairs or groups of carbons related to each other by symmetry which therefore give only one signal. The very strong signal at $\delta = 30.4$ ppm belongs to the six identical methyl groups on the $t$-butyl groups (coloured red) and the other two signals in the 0–50 ppm range are the methyl group at C4 and the brown central carbons of the $t$-butyl groups. In the aromatic region there are only four signals as the two halves of the molecule are the same. As with the last example, we are not concerned with exactly which is which—we just check that there are the right number of signals with the right chemical shifts.

Paracetamol is a familiar painkiller with a simple structure—it too is a phenol but in addition it carries an amide substituent on the benzene ring. Its NMR spectrum contains one saturated carbon atom at 24 ppm (the methyl group of the amide side chain), one carbonyl group at 168 ppm, and four other peaks at 115, 122, 132, and 153 ppm. These are the carbons of the benzene ring. Why four peaks? The two halves of the benzene ring must be the same (only one signal for each pair of carbons coloured red and green), which tells us that the NHCOCH3 group doesn’t really lie just to one side as shown here, but rotates rapidly, meaning that on average the two sides of the ring are indistinguishable, as in BHT. Why is one of these aromatic peaks in the C=O region at 153 ppm? This must be C4 because it is bonded to oxygen, a reminder that carbonyl groups are not the only unsaturated carbon atoms bonded to oxygen (see the chart on p. 56), although it is not as deshielded as the true C=O group at 168 ppm.
The $^1$H NMR spectrum

$^1$H NMR (or ‘proton NMR’) spectra are recorded in the same way as $^{13}$C NMR spectra: radio waves are used to study the energy level differences of nuclei, but this time they are $^1$H and not $^{13}$C nuclei. Like $^{13}$C, $^1$H nuclei have a nuclear spin of 1/2 and so have two energy levels: they can be aligned either with or against the applied magnetic field. Here, as an example, is the $^1$H NMR spectrum of acetic (ethanoic) acid, MeCO$_2$H, and below it the $^{13}$C NMR spectrum.

$^1$H NMR spectra have many similarities with $^{13}$C NMR spectra: the scale runs from right to left and the zero point is given by the same reference compound, though it is the proton resonance of Me$_4$Si rather than the carbon resonance that defines the zero point. However, as you immediately see in the spectrum above, the scale is much smaller, ranging over only about 10 ppm instead of the 200 ppm needed for carbon. This makes perfect sense: the variation in the chemical
shift is a measure of the shielding of the nucleus by the electrons around it. There is inevitably less change possible in the distribution of two electrons around a hydrogen nucleus than in that of the eight valence electrons around a carbon nucleus. Nonetheless the acetic acid spectrum above shows you that, just as you would expect, the H atom of the carboxylic acid group, directed attached to an oxygen atom, is more deshielded than the H atoms of acetic acid’s methyl group.

We can also divide up the $^1H$ NMR spectrum into regions that parallel the regions of the $^{13}C$ NMR spectrum. Hydrogen atoms bonded to saturated carbon atoms appear in the right-hand, more shielded (between 5 and 0 ppm) region of the spectrum, while those bonded to unsaturated carbon atoms (alkenes, arenes, or carbonyl groups primarily) appear in the left-hand, less shielded region between 10 and 5 ppm. As with the $^{13}C$ spectrum, nearby oxygen atoms withdraw electron density and make the signals appear towards the left-hand end of each of these regions.

Some examples of $^1H$ NMR spectra

You can see exactly how $^1H$ NMR signals fall into these regions in the following collection of spectra. The first two spectra each contain only one peak because every proton in benzene and in cyclohexane is identical. In benzene the peak is at 7.5 ppm, where we expect a proton attached to an unsaturated C atom to lie, while in cyclohexane it is at 1.35 ppm because all the cyclohexane protons are attached to saturated C atoms. Again, to help comparisons, we have also included the $^{13}C$ spectra of benzene and cyclohexane. For benzene, the signal falls in the unsaturated C region (100–150 ppm), at 129 ppm, while for cyclohexane it is in the saturated C region, at 27 ppm.
tert-Butyl methyl ether is a solvent and fuel additive whose $^1$H spectrum illustrates the effect of a nearby oxygen atom: the large peak at 1.1 ppm comes from the nine H atoms making up three identical methyl groups of the tert-butyl part of the molecule, while the three H atoms of the methyl part of the ether are at 3.15 ppm. These three hydrogen atoms are all bonded directly to a C atom, which itself is bonded to O, whose electronegativity attracts their electrons, deshielding the $^1$H nuclei and shifting them to larger chemical shift.

The plane of symmetry we noted in the $^{13}$C NMR spectrum of BHT means that the $^1$H NMR spectrum of the related compound Topanol 354 is relatively simple for a compound with 26 H atoms: a large peak and two small peaks between 5 and 0 ppm for the 18 protons of the tert-butyl groups and the three protons of each methyl group, and another small peak between 5 and 10 ppm for the two protons attached to the aromatic ring.

Each alcohol has a saturated carbon atom next to oxygen, all appearing in the region typical of saturated carbon atoms next to oxygen (p. 56). Then there are carbons next door but one to oxygen: they are back in the 0–50 ppm region but at its low field end—about 30–35 ppm—because they are still deshielded by the nearby oxygen atom. Two of the alcohols have carbon(s) one further away still at yet smaller chemical shift (further upfield, more shielded) at about 20 ppm, but only the n-butanol has a more remote carbon still at 15.2. The number and the chemical shift of the signals identify the molecules very clearly.

A common situation chemists find themselves in is that they have some idea about a molecular formula—from high-resolution mass spectrometry, for example—and need to match a structure to NMR data. Here’s an example: the formula C₃H₆O is represented by seven reasonable structures, as shown in the margin. The three ¹³C NMR spectra below represent three of these compounds. The challenge is to identify which three. We will give you some clues, and then we suggest you try to work out the answer for yourself before turning the page.

Simple symmetry can distinguish structures A, C, and E from the rest as these three have only two types of carbon atom. The two carbonyl compounds, D and E, will have one peak in the 150–200 ppm region but D has two different saturated carbon atoms while E has only one. The two alkenes, F and G, both have two unsaturated carbon atoms (100–200 ppm) but in ether G one of them is joined to oxygen—you would expect it therefore to be deshielded and to appear between 150 and 200 ppm.

NMR is a powerful tool for solving unknown structures

To illustrate the power of NMR, consider these three alcohols of formula C₄H₁₀O, each of which has a quite different ¹³C NMR spectrum. Peaks from the spectra are shown in the table below.

The meanings of n-, iso-, and tert- were covered in Chapter 2 (p. 26).
The three saturated compounds (A, B, and C) present the greatest problem. The epoxide, B, has two different carbon atoms next to oxygen (50–100 ppm) and one normal saturated carbon atom (0–50 ppm). The remaining two both have one signal in the 0–50 ppm region and one in the 50–100 ppm region, and only the more powerful techniques of $^1$H NMR and, to a certain extent, infrared spectroscopy (which we will move on to shortly) will distinguish them reliably.

Here are NMR spectra of three of these molecules. Before reading further see if you can assign them to the structures on the previous page. Try also to suggest which signals belong to which carbon atoms.

We hope these didn’t give you too much trouble. The only carbonyl compound with two identical carbons is acetone (E) so spectrum 1 must be that one. Notice the very low field signal (206.6 ppm) typical of a simple ketone C=O carbon atom. Spectrum 2 has two unsaturated carbons and a saturated carbon next to oxygen so it must be F or G. In fact it has to be F as both unsaturated carbons are similar (137 and 116 ppm) and neither is next to oxygen (>150 ppm). This leaves spectrum 3, which appears to have no carbon atoms next to oxygen as all chemical shifts are less than 50 ppm. No compound fits that description and the two signals at 48.0 and 48.2 ppm are suspiciously close to the arbitrary 50 ppm borderline. They are, of course, both next to oxygen and this is compound B.

**Infrared spectra**

**Functional groups are identified by infrared spectra**

$^{13}$C and $^1$H NMR spectra tell us a lot about the hydrocarbon skeleton of a molecule, and mass spectroscopy weighs the molecule as a whole. But none of these techniques reveal much about functional groups. Some functional groups, for example C=O or C=C, can be seen in the $^{13}$C NMR spectrum because they contain carbon atoms, but many, such as ethers or nitro groups, cannot be seen at all by NMR—they show their presence only by the way they affect the chemical shifts of nearby H or C atoms.
Infrared (IR) spectroscopy, however, provides a direct way of observing these functional groups because it detects the stretching and bending of bonds rather than any property of the atoms themselves. It is particularly good at detecting the stretching of unsymmetrical bonds of the kind found in functional groups such as OH, C=O, NH$_2$, and NO$_2$, and for this reason IR spectroscopy complements NMR beautifully as a method for structural analysis.

NMR requires electromagnetic waves in the radio-wave region of the spectrum to make nuclei flip from one state to another. The amount of energy needed for stretching and bending individual bonds, while still very small, is rather greater, and therefore corresponds to much shorter wavelengths. These wavelengths lie in the infrared, just to the long wavelength side of visible light (wavelengths between 10 and 100 mm). When the carbon skeleton of a molecule vibrates, all the bonds stretch and relax in combination and by and large these absorptions are unhelpful. However, some bonds stretch essentially independently of the rest of the molecule, and we can use these to identify functional groups. This occurs if the bond is either:

- much stronger or weaker than others nearby, or
- between atoms that are much heavier or lighter than their neighbours

Indeed, the relationship between the frequency of the bond vibration, the mass of the atoms, and the strength of the bond is essentially the same as Hooke’s law for a simple harmonic oscillator. Hooke’s law shows that the frequency of the vibration $\nu$ is proportional to the square root of a force constant $f$—more or less the bond strength—and inversely proportional to the square root of a reduced mass $\mu$, that is, the product of the masses of the two atoms forming the bond divided by their sum:

$$\mu = \frac{m_1 m_2}{m_1 + m_2}$$

The precise maths is less important to us as chemists than the simple result.

- **Stronger bonds vibrate faster and so do lighter atoms.**

Infrared spectra are simple absorption spectra. The sample is dissolved in a solvent (or sometimes deposited on the surface of an inert NaCl plate) and exposed to infrared radiation. The wavelength scanned across the spectrum and the amount of infrared energy able to pass through the sample are plotted against the wavelength of the radiation. Just to make the numbers work out nicely, IR spectra don’t usually indicate the wavelength but instead a value known as the ‘wavenumber’, in cm$^{-1}$, which is simply the number of wavelengths in one centimetre. For a typical bond this will fall between 4000 (short wavelengths, i.e. high frequency) and 500 (long wavelengths, i.e. low frequency). Strong bonds, and light atoms, vibrate fast, so you expect to see these bonds at the high wavenumber end of the spectrum, always plotted at the left-hand end.

To illustrate what we mean, here are some typical values for the IR frequencies of a selection of bonds grouped in two ways. Firstly, a series of bonds to increasingly heavy atoms (D, deuterium, has twice the mass of H, and Cl has about twice the mass of O) and secondly a series of bonds of increasing strength.

**Hooke’s law** describes the movement of two masses attached to a spring. You may have met it if you have studied physics. You need not be concerned here with its derivation, just the result. It takes the following form:

$$\nu = \frac{1}{2\pi}\sqrt{\frac{f}{\mu}}$$

where $\nu$ is the frequency, $f$ is the force constant and $\mu$ is the reduced mass. $c$ is a constant needed to make the units work.
Here’s what a typical IR spectrum actually looks like: notice that the wavenumber scale runs from high to low but also that absorption maxima are shown upside down (IR spectra plot 'transmission')—you might say that IR spectra are upside down and back to front. If you look carefully you will also see that the scale changes in the middle to give more space to the more detailed right-hand half of the spectrum.

This is the spectrum of cyanoacetamide, the compound shown on the right. The overall shape of the spectrum is characteristic of this compound, but as chemists we need to be able to interpret the spectrum, and we can do this by dividing it up into regions, just as we did with the NMR spectra.

There are four important regions of the infrared spectrum

The first region, from 4000 to 2500 cm⁻¹ is the region for C–H, N–H, and O–H bond stretching. Most of the atoms in an organic molecule (C, N, O, for example) are about the same weight (12, 14, 16...). Hydrogen is an order of magnitude lighter than any of these and so it dominates the stretching frequency by the large effect it has on the reduced mass, so any bond to H comes right at the left-hand end of the spectrum.

Even the strongest bonds between non-H atoms—triple bonds such as C≡C or C≡N—absorb at slightly lower frequencies than bonds to hydrogen: these are in the next region, the triple bond region from about 2500 to 2000 cm⁻¹. This and the other two regions of the spectrum follow in logical order of bond strength as the reduced masses are all about the same: C=C and C=O double bonds appear about 2000–1500 cm⁻¹ and at the right-hand end of the spectrum come single bonds, below 1500 cm⁻¹. These regions are summarized in this chart, which you should memorize.

**Reduced mass and atomic mass**

We introduced the idea of reduced mass on p. 64. To illustrate the effect of H on reduced mass, consider this: the reduced mass of a C–C bond is (12*12)/(12+12), i.e. 144/24 = 6.0. If we change one of these atoms for H, the reduced mass changes to (12*1)/(12+1), i.e. 12/13 = 0.92, but if we change it instead for F, the reduced mass changes to (12*19)/(12+19), i.e. 228/31 = 7.35. There is a small change when we increase the mass to 19 (F), but an enormous change when we decrease it to 1 (H).
Looking back at the spectrum of cyanoacetamide on p. 65, we see peaks in the X–H region at about 3300 and 2950 cm$^{-1}$, which are the N–H and C–H stretches of the NH$_2$ and CH$_2$ groups. The one rather weak peak in the triple bond region (2270 cm$^{-1}$) is the C≡N group and the strong peak at about 1670 cm$^{-1}$ belongs to the C=O group. We shall explain soon why some IR peaks are stronger than others. The rest of the spectrum is in the single bond region. This region is not normally interpreted in detail but is characteristic of the compound as a whole rather in the way that a fingerprint is characteristic of an individual human being—similarly, it cannot be interpreted. It is indeed called the fingerprint region. The useful information from this spectrum is the presence of the C≡N and C=O groups and the exact position of the C=O absorption.

**The X–H region (4000–3000 cm$^{-1}$) distinguishes C–H, N–H, and O–H bonds**

The reduced masses of the C–H, N–H, and O–H combinations are all about the same. Any difference between the positions of the IR bands of these bonds must then be due to bond strength. In practice, C–H stretches occur at around 3000 cm$^{-1}$ (although they are of little use in identifying compounds, it’s a rare organic compound that has no C–H bonds), N–H stretches occur at about 3300 cm$^{-1}$, and O–H stretches higher still at around 3500 cm$^{-1}$. We can immediately deduce that the O–H bond is stronger than N–H, which is stronger than C–H. IR is a good way to measure such bond strengths.

$^a$When not hydrogen-bonded: see below.

The form of the absorption bands resulting from X–H IR stretches are very different in these four compounds. Have a look at the shaded portions of the following spectra:
The IR peak of an NH group looks different (spectrum 1) from that of an NH₂ group (spectrum 2). A bond gives an independent vibration only if both bond strength and reduced mass are different from those of neighbouring bonds. In the case of an isolated N–H group, this is likely to be true and we usually get a sharp peak at about 3300 cm⁻¹, whether the NH group is part of a simple amine (R₂NH) or an amide (RCONHR). The NH₂ group is also independent of the rest of the molecule, but the two NH bonds inside the NH₂ group have identical force constants and reduced masses, and so vibrate as a single unit. Two equally strong bands appear: one for the two N–H bonds vibrating in phase (symmetric) and one for the two N–H bonds vibrating in opposition (antisymmetric). The antisymmetric vibration requires more energy and is at slightly higher frequency.

The O–H bands occur at higher frequency, sometimes as a sharp absorption at about 3600 cm⁻¹. More often, as in spectra 3 and 4, you will see a broad absorption at anywhere from 3500 to 2900 cm⁻¹. This is because OH groups form strong hydrogen bonds that vary in length and strength. A sharp absorption at 3600 cm⁻¹ indicates a non-hydrogen-bonded OH group; the lower the absorption frequency the stronger the H bond.

Alcohols form hydrogen bonds between the hydroxyl oxygen of one molecule and the hydroxyl hydrogen of another. These bonds are variable in length (although they are usually rather longer than normal covalent O–H bonds) and they slightly weaken the true covalent O–H bonds by varying amounts. When a bond varies in length and strength it will have a range of stretching frequencies distributed about a mean value. Alcohols, including the phenol shown in spectrum 3, typically give a rounded absorption at about 3300 cm⁻¹ (contrast the sharp shape of the N–H stretch in the same region you see in the spectra above). Carboxylic acids (RCO₂H) form hydrogen-bonded dimers with two strong H bonds between the carbonyl oxygen atom of one molecule and the acidic hydrogen of the other. These also vary considerably in length and strength, and usually give the very broad V-shaped absorbance you see in the benzoic acid spectrum 4.
The spectra of paracetamol and BHT (which you met on pp. 58–59) illustrate the effect of hydrogen bonding on peak shape. Paracetamol has a typical sharp peak at 3330 cm\(^{-1}\) for the N–H stretch and then a rounded absorption for the hydrogen-bonded O–H stretch from 3300 down to 3000 cm\(^{-1}\) in the gap between the N–H and C–H stretches. By contrast, BHT has a sharp absorption at 3600 cm\(^{-1}\) as the two large \(t\)-butyl groups prevent the typical hydrogen bond from forming.

You may be confused the first time you see the IR spectrum of a terminal alkyne, \(R–C≡C–H\), because you will see a strongish sharp peak at around 3300 cm\(^{-1}\) that looks just like an N–H stretch—the spectrum below (of methyl propynoate, also known as methyl propiolate) illustrates this. The displacement of this peak from the usual C–H stretch at about 3000 cm\(^{-1}\)
cannot be due to a change in the reduced mass and must be due to a marked increase in bond strength. The alkyne C–H bond is shorter and stronger than alkane C–H bonds.

The triple bond region (3000–2000 cm$^{-1}$)

This region is often empty, meaning that when you do see a peak between 2000 and 2500 you can be absolutely certain that the compound is an alkyne (usually at around 2100) or a nitrile (at 2250 cm$^{-1}$). There are examples above and on p. 65.
The double bond region is the most important in IR spectra

The most important absorptions in the double bond region are those of the carbonyl (C=O), alkene or arene (C=C), and nitro (NO₂) groups. All give rise to sharp bands, C=O gives one strong (i.e. intense) band anywhere between 1900 and 1500 cm⁻¹; alkene C=C gives one weak band at about 1640 cm⁻¹, and NO₂ gives two strong (intense) bands in the mid-1500s and mid-1300s cm⁻¹. Arenes usually give two or three bands in the region 1600–1500 cm⁻¹. We can illustrate several of these features in the spectrum shown below, which is that of 4-nitrocinnamaldehyde, shown in the margin.

![4-nitrocinnamaldehyde](image)

Why the nitro group gives two bands is easily understood. Just as with OH and NH₂, it is a matter of how many identical bonds are present in the same functional group. Carbonyl and alkene clearly have one double bond each. The nitro group at first sight appears to contain two different groups, N⁺–O⁻ and N=O, but delocalization means they are identical and we see absorption for symmetric and antisymmetric stretching vibrations. As with NH₂, more energy is associated with the antisymmetric vibration and it occurs at higher frequency (>1500 cm⁻¹).

Arenes, being rings, have a much more complex pattern of vibration that cannot be analysed simply. However, it’s worth noting that arene C=C bonds come at lower frequency (<1600 cm⁻¹) than alkene C=C bonds (>1600 cm⁻¹). Why? Well the individual C–C bonds in benzene are of course not full C=C double bonds—all six bonds are the same, and have the averaged character of one-and-a-half bonds each. Not surprisingly, the absorptions of these bonds fall right on the boundary between the single and double bond regions.

You’ve already seen the IR spectra of the three carbonyl compounds below in this chapter. It’s easy to identify the C=O peak in each spectrum—C=O peaks are always intense (you will see why in a minute) and come somewhere near 1700 cm⁻¹.

**The strength of an IR absorption depends on dipole moment**

If you look back at the X–H regions (3000–4000 cm⁻¹) of the four spectra on pp. 66–67, you’ll notice something that at first sight seems odd. The N–H and O–H absorptions are stronger than the C–H absorptions at 3000 cm⁻¹, despite there being more C–H bonds in these molecules than O–H or N–H bonds. The reason for this is that the strength of an IR absorption varies with the change of dipole moment (see the box below for a definition) when the bond is stretched. If the bond is perfectly symmetrical, there is no change in dipole moment and there is no IR absorption. Obviously, the C=C bond is less polar than either C=O or N=O and its absorption is less intense in the IR. Indeed it may be absent altogether in a symmetrical alkene. By contrast the carbonyl group is very polarized, with oxygen attracting the electrons away from carbon, and stretching it causes a large change in dipole moment. C=O stretches are usually the strongest peaks in the IR spectrum. O–H and N–H stretches are stronger than C–H stretches because C–H bonds are only weakly polarized.

**Dipole moments**

Dipole moment depends on the variation in distribution of electrons along the bond and also its length, which is why stretching a bond can change its dipole moment. For bonds between unlike atoms, the larger the difference in electronegativity, the greater the dipole moment and the more it changes when stretched. For identical atoms (C=C, for example) the dipole moment, and its capacity to change with stretching, is much smaller. Stretching frequencies for symmetrical molecules can be measured using an alternative method known as Raman spectroscopy. This is an IR-based technique using scattered light that relies on the polarizability of bonds. Raman spectra are outside the scope of this book.

This is a good point to remind you of the various deductions we have made so far about IR spectra.

The single bond region is used as a molecular fingerprint

The region below 1500 cm$^{-1}$ is where the single bond vibrations occur. Here our hope that individual bonds may vibrate independently of the rest of the molecule is usually doomed to disappointment. The atoms C, N, and O all have about the same atomic weight and C–C, C–N, and C–O single bonds all have about the same strength.

<table>

</tr>
</tbody>
</table>

In addition, C–C bonds are often joined to other C–C bonds with virtually identical strength and reduced mass, and they have essentially no dipole moments. The only one of these single bonds of any value is C–O, which is polar enough to show up as a strong absorption at about 1100 cm$^{-1}$. Some other single bonds, such as C–Cl (weak and with a large reduced mass, so appearing at low frequency), are quite useful at about 700 cm$^{-1}$. Otherwise the single bond region is usually crowded with hundreds of absorptions from vibrations of all kinds used as a ‘fingerprint’ characteristic of the molecule but not really open to interpretation.

Among those hundreds of peaks in the fingerprint region there are some of a quite different kind. Stretching is not the only bond movement that leads to IR absorption. Bending of bonds, particularly C–H and N–H bonds, also leads to quite strong peaks. These are called deformations. Bending a bond is easier than stretching it (which is easier, stretching or bending an iron bar?). Consequently, bending absorptions need less energy and come at lower frequencies than stretching absorptions for the same bonds. These bands may not often be useful in identifying molecules, but you will notice them as they are often strong (they are usually stronger than C=C stretches, for example) and may wonder what they are.

Mass spectra, NMR, and IR combined make quick identification possible

If these methods are each as powerful as we have seen on their own, how much more effective they must be together! We shall finish this chapter with the identification of some simple unknown compounds using all three methods. The first is an industrial emulsifier used to blend solids and liquids into smooth pastes. Its electrospray mass spectrum shows it has $M + H$ with a mass of 90, so an odd molecular weight (89) suggests one nitrogen atom. High-resolution mass spectrometry reveals that the formula is C$_3$H$_7$NO.
The $^{13}$C NMR spectrum has only three peaks so two of the carbon atoms must be the same. There is one signal for saturated carbon next to oxygen, and two for other saturated carbons, one more downfield than the other.

The IR spectrum reveals a broad peak for an OH group with two sharp NH$_2$ peaks just protruding. If we put this together, we know we have C–OH and C–NH$_2$. Neither of these carbons can be duplicated (as there is only one O and only one N) so it must be the other two C atoms that are the same.
The next stage is one often overlooked. We don’t seem to have much information, but try and put the two fragments together, knowing the molecular formula, and there’s very little choice. The carbon chain (shown in red) could either be linear or branched and that’s it!

There is no room for double bonds or rings because we need to fit in the 11 hydrogen atoms. We cannot put N or O in the chain because we know from the IR that we have the groups OH and NH$_2$, which can each be joined only to one other group. Of the seven possibilities only the last two, A and B, are possible since they alone have two identical carbon atoms (the two methyl groups in each case); all the other structures would have four separate signals in the NMR.

So, how can we choose between these? The solution is in the $^1$H NMR spectrum, which is shown below. There are only two peaks visible: one at 3.3 and one at 1.1 ppm. It’s quite common in $^1$H NMR spectra not to see signals for protons attached to O or N (you will see why in Chapter 13) so we can again rule out all structures with more than two different types of H attached to C. Again, we are left with A and B, confirming our earlier deductions. But the chemical shift of the signal at $\delta$ 3.3 tells us more: it has to be due to H atoms next to an oxygen atom because it is deshielded. The industrial emulsifier must therefore be A: 2-amino-2-methylpropan-1-ol.

Double bond equivalents help in the search for a structure

The last example was fully saturated but it is usually a help in deducing the structure of an unknown compound if, once you know the atomic composition, you immediately work out how much unsaturation there is. It may seem obvious to you that, as C$_4$H$_{11}$NO has no double bonds, then C$_4$H$_9$NO (losing two hydrogen atoms) must have one double bond, C$_4$H$_7$NO two double bonds, and so on. Well, it’s not quite as simple as that. Some possible structures for these formulae are shown below.
Some of these structures have the right number of double bonds (C=C and C=O), one has a triple bond, and three compounds use rings as an alternative way of ‘losing’ some hydrogen atoms. Each time you make a ring or a double bond, you have to lose two more hydrogen atoms. So double bonds (of all kinds) and rings are called **double bond equivalents** (DBEs).

You can work out how many DBEs there are in a given atomic composition just by making a drawing of one possible structure for the formula (all possible structures for the same formula have the same number of DBEs). Alternatively, you can calculate the DBEs if you wish. A saturated hydrocarbon with \( n \) carbon atoms has \((2n + 2)\) hydrogens. Oxygen doesn’t make any difference to this: there are the same number of Hs in a saturated ether or alcohol as in a saturated hydrocarbon.

So, for a compound containing C, H, and O only, take the actual number of hydrogen atoms away from \((2n + 2)\) and divide by two. Just to check that it works, for the unsaturated ketone \( \text{C}_7\text{H}_{12}\text{O} \) the calculation becomes:

1. Maximum number of H atoms for 7Cs: \(2n + 2 = 16\)
2. Subtract the actual number of H atoms (12): \(16 – 12 = 4\)
3. Divide by 2 to give the DBEs: \(4/2 = 2\)

Here are two more examples to illustrate the method. This unsaturated cyclic acid has: 16 – 10 = 6 divided by 2 = 3 DBEs and it has one alkene, one C=O, and one ring. Correct.

The aromatic ether has 16 – 8 = 8 divided by 2 gives 4 DBEs and it has three double bonds in the ring and the ring itself. Correct again. A benzene ring always gives four DBEs: three for the double bonds and one for the ring.

Nitrogen makes a difference. Every nitrogen adds one extra hydrogen atom because nitrogen can make three bonds. This means that the formula becomes: subtract actual number of hydrogens from \((2n + 2)\), add one for each nitrogen atom, and divide by two. We can try this out too. Here are some example structures of compounds with seven C atoms, one N and an assortment of unsaturation and rings.

The saturated compound has \((2n + 3)\) Hs instead of \((2n + 2)\). The saturated nitro compound has \((2n + 2) = 16\), less 15 (the actual number of Hs) plus one (the number of nitrogen atoms) = 2.
Divide this by 2 and you get 1 DBE, which is the N=O bond. We leave the third and fourth examples for you to work out, but the last compound (we shall meet this later as DMAP) has:

1. Maximum number of H atoms for 7Cs: \(2n + 2 = 16\)
2. Subtract the actual number of H atoms (10): \(16 - 10 = 6\)
3. Add number of nitrogens: \(6 + 2 = 8\)
4. Divide by 2 to give the DBEs: \(8/2 = 4\)

There are indeed three double bonds and a ring, making four in all. Make sure that you can do these calculations without much trouble.

If you have other elements too it is simpler just to draw a trial structure and find out how many DBEs there are. You may prefer this method for all compounds as it has the advantage of giving you one possible structure before you really start. One good tip is that if you have few hydrogens relative to the number of carbon atoms (at least four DBEs) then there is probably an aromatic ring in the compound.

Knowing the number of double bond equivalents for a formula derived by high-resolution mass spectrometry is a quick short cut to generating some plausible structures. You can then rule them in or rule them out by comparing with IR and NMR data.

**Working out the DBEs for an unknown compound**

1. Calculate the expected number of Hs in the saturated structure
   
   (a) For \(C_n\) there would be \(2n + 2\) H atoms if C, H, O only.
   
   (b) For \(C_nN_m\) there would be \(2n + 2 + m\) H atoms.
2. Subtract the actual number of Hs and divide by 2. This gives the DBEs.
3. If there are other atoms (Cl, B, P, etc.) it is best to draw a trial structure.
4. A DBE indicates either a ring or a double bond (a triple bond is two DBEs).
5. A benzene ring has four DBEs (three for the double bonds and one for the ring).
6. If there are few Hs, e.g. less than the number of Cs, suspect a benzene ring.
7. A nitro group has one DBE only.

**An unknown compound from a chemical reaction**

Our last example addresses a situation very common in chemistry—working out the structure of a product of a reaction. The situation is this: you have treated propenal (acrolein) with HBr in ethane-1,2-diol (or glycol) as solvent for 1 hour at room temperature. Distillation of the reaction mixture gives a colourless liquid, compound X. What is it?
The mass spectrum shows a molecular ion (181) much heavier than that of the starting material, $C_3H_4O = 56$. Indeed it shows two molecular ions at 181 and 179, typical of a bromo compound, so it looks as if HBr has added to the aldehyde somehow. High resolution mass spectrometry reveals a formula of $C_5H_9BrO_2$, and the five carbon atoms make it look as though the glycol has added in too. If we add everything together we find that the unknown compound is the result of the three reagents added together less one molecule of water.

Now, how many DBEs have we got? With a formula like this the safest bet is to draw something that has the right formula—it need not be what you expect the product to be. Here’s something in the margin—we just added atoms till we got there, and to do so we had to put in one double bond. $C_5H_9BrO_2$ has one DBE.

The next thing is to see what remains of the hydrocarbon skeleton of propenal by NMR. The $^{13}$C NMR spectrum of $\text{CH}_2\text{CHO}$ clearly shows one carbonyl group and two carbons on a double bond. These have all disappeared in the product and for the five carbon atoms we are left with four signals, two saturated, one next to oxygen, and one at 102.6 ppm, just creeping into the double bond region.

The IR spectrum gives us another puzzle—there appear to be no functional groups at all! No OH, no carbonyl, no alkene—what else can we have? The answer is an ether, or rather two ethers as there are two oxygen atoms. Now that we suspect an ether, we can look for the C–O single bond stretch in the IR spectrum and find it at 1128 cm$^{-1}$. 

It's often very helpful, when you have an unknown product, to subtract the molecular mass of the starting material from its molecular mass to find out what has been added (or taken away).
Each ether oxygen must have a carbon atom on each side of it, but we seem to have only one carbon in the saturated C next to O region (50–100 ppm) in the $^{13}$C NMR. Of course, as you’ve already seen, these limits are arbitrary, and in fact the peak at 102 ppm is also a saturated C next to O. It is unlikely to be an alkene anyway as it takes two carbons to make an alkene. What would deshield a saturated C as much as this? The answer is two oxygen atoms. We can explain the $^{13}$C spectrum if we assume a symmetrical fragment C—O—C—O—C accounts for three of the five carbon atoms.

So, where is our double bond equivalent? We know we haven’t got a double bond (no alkene and no C=O) so the DBE must be a ring. You might feel uncomfortable with rings, but you must get used to them. Five-, six-, and seven-membered rings are very common. In fact, most known organic compounds have rings in them. We could draw many cyclic structures for the formula we have here, such as this one in the margin.

But this won’t do as it would have five different carbon atoms. It is much more likely that the basic skeletons of the organic reagents are preserved, that is, that we have a two-carbon (from the ethylene glycol) and a three-carbon (from the propenal) fragment joined through oxygen atoms. This gives four possibilities, all containing the C—O—C—O—C fragment we deduced earlier (highlighted in black).

These are all quite reasonable, although we might prefer the third as it is easier to see how it derives from the reagents. The product is in fact this third possibility, and to be sure we would have to turn to the fine details of $^1$H NMR spectroscopy, which we return to in Chapter 13.

**Looking forward to Chapters 13 and 18**

We have only begun to explore the intricate world of identification of structure by spectroscopy. It is important that you recognize that structures are assigned, not because of some theoretical reason or because a reaction ‘ought’ to give a certain product, but because of sound evidence from spectra. You have seen four powerful methods—mass spectra, $^{13}$C and $^1$H NMR, and IR spectroscopy—in this chapter. In Chapter 13 we delve more deeply into the most important of all ($^1$H NMR) and, finally, in Chapter 18 we shall take each of these methods a little further and show how the structures of more complex unknown compounds are really deduced. The last problem we have discussed here is not really solvable without $^1$H NMR and in reality no-one would tackle any structure problem without this most powerful of all techniques. From now on spectroscopic evidence will appear in virtually every chapter. Even if we do not say so explicitly every time a new compound appears, the structure of this compound will in fact have been determined spectroscopically. Chemists make new compounds, and every time they do they characterize the compound with a full set of spectra. No scientific journal will accept that a new compound has been made unless a full description of all of these spectra are submitted with the report. Spectroscopy lets the science of organic chemistry advance.

- NMR involves molecular orbitals ch13

Introduction

You may recognize the model above as DNA, the molecule that carries the genetic instructions for making all life on earth. The helical shape of DNA was discovered in 1953, and the detailed arrangement of atoms in the DNA molecule determines whether it is a recipe for an ant, an antelope, an antirrhinum, or anthrax.

You may also have recognized this molecule as buckminsterfullerene, a soccer-ball shaped allotrope of carbon. Buckminsterfullerene, named after the architect of the geodesic dome (which it resembles), was first identified in 1985 and earned its discoverers the Nobel Prize for chemistry in 1996.
Now, our question is this: how did you recognize these two compounds? You recognized their *shapes*. Molecules are not simply a jumble of atoms: they are atoms held together in a defined three-dimensional shape. A compound’s properties are determined not only by the atoms it contains, but also by the spatial arrangement of these atoms. Graphite and diamond—the two other allotropes of carbon—are both composed only of carbon atoms and yet their properties, both chemical and physical, are completely different because those carbon atoms are arranged very differently. Graphite has carbon atoms arranged in sheets of hexagons; diamond has them arranged in a tetrahedral array.

We know what shapes molecules have because we can see them—not literally of course, but by methods such as atomic force microscopy (AFM). AFM reveals the shape of pentacene, the molecule we would usually draw as the structure below, to be as shown on the left. This is the closest we can get to actually ‘seeing’ the atoms themselves.

Most analytical techniques reveal the shapes of molecules less directly. X-ray diffraction gives information about the arrangement of atoms in space, while the other spectroscopic methods you met in Chapter 3 reveal details of the composition of molecules (mass spectrometry) or the connectivity of the atoms they contain (NMR and IR).

From methods such as these, we know what shapes molecules have. This is why we urged you in Chapter 2 to make your drawings of molecules realistic—we can do this because we know what is realistic and what isn’t. But now we need to tackle the question of *why* molecules have the shapes they do. What is it about the properties of their constituent atoms which dictates those shapes? We will find that the answer not only allows us to explain and predict structure, but also allows us to explain and predict reactivity (which forms the topic of Chapter 5).

First of all, we need to consider why atoms form molecules at all. Some atoms (helium, for example) do so only with extreme reluctance, but the vast majority of atoms in the periodic table are much more stable in molecules than as free atoms. Here, for example, is methane: four hydrogen atoms arranged around a carbon in the shape of a tetrahedron.
Molecules hold together because positively charged atomic nuclei are attracted to negatively charged electrons, and this fact allows electrons to act as ‘glue’ between the nuclei. The C and H nuclei of methane are of course positively charged, but the ten electrons (a total of six from C, four from the H atoms) bind those positive charges into a molecular structure. Ammonia (NH₃) and water (H₂O) also have ten electrons in total, and we know that their molecular shapes are in fact just like that of methane, but with one or two hydrogen atoms removed.

This tells us something important: it is the number of electrons which determines the shape of a molecule, and not just the number of atoms (or atomic nuclei). But what determines how electrons are arranged? Why do ten electrons give rise to a tetrahedron, for example?

Before we can answer this question, we need to simplify our discussion a bit and think about electrons not in molecules but in individual atoms. We can then approximate the electronic structure of molecules by considering how the component atoms combine. It is important to remember throughout this chapter, however, that molecules are only very rarely ‘made’ directly by joining atoms together. What we are going to present is an analysis of the structure of molecules, not a discussion of ways to build them (to which we will devote much of the later part of this book). Much of what we will cover was worked out in the decades around 1900, and it all came from experimental observation. Quantum theory explains the details, and you can read much more about it in a textbook of physical chemistry. Our aim here is to give you enough of an understanding of the theory to be able to use sound principles to predict and explain the structure of organic molecules.

So, first, some evidence.

Atomic emission spectra

Many towns and streets are lit at night by sodium vapour lamps, which emit an intense, pure yellow-orange glow. Inside these lights is sodium metal. When the light is switched on, the sodium metal is slowly vaporized. As an electric current is passed through the sodium vapour, an orange light is emitted—the same colour as the light you get when you put a small amount of a sodium compound on a spatula and place it in a Bunsen flame. Given sufficient energy (from the electric current or from a flame) sodium always emits this same wavelength of light, and it does so because of the way the electrons are arranged in a sodium atom. The energy supplied causes an electron to move from a lower energy state to a higher energy, or excited, state, and as it drops down again light is emitted. The process is a bit like a weight-lifter lifting a heavy weight—he can hold it above his head with straight arms (the excited state) but sooner or later he will drop it and the weight will fall to the ground, releasing energy with a crash, if not a broken toe. This is the origin of the lines in the atomic spectra not only for sodium but for all the elements. The flame or the electric discharge provides the energy to promote an electron to a higher energy level and, when this electron returns to its ground state, this energy is released in the form of light.

If you refract the orange sodium light through a prism, you see a series of very sharp lines, with two particularly bright ones in the orange region of the spectrum at around 600 nm. Other elements produce similar spectra—even hydrogen, and since a hydrogen atom is the simplest atom of all, we shall look at the atomic spectrum of hydrogen first.

Electrons have quantized energy levels

The absorption spectrum for hydrogen was first measured in 1885 by a Swiss schoolmaster, Johann Balmer, who also noticed that the wavelengths of the lines in this spectrum could be predicted using a mathematical formula. You do not need to know the details of his formula at this stage, instead let’s think about the implications of the observation that a hydrogen atom, with just one electron, has a spectrum of discrete lines at precise wavelengths. It means
that the electron can only occupy energy levels with precisely determined values, in other
words that the energy of an electron orbiting a proton (a hydrogen nucleus) is quantized. The
electron can have only certain amounts of energy, and therefore the gaps between these
energy levels (which give rise to the spectrum) likewise can only have certain well-defined
values. Think of climbing a flight of stairs—you can jump up one, two, five, or even all the
steps if you are energetic enough, but you cannot climb up half or two-thirds of a step.
Likewise coming down, you can jump from one step to any other—lots of different combina-
tions are possible but there is a finite number, depending on the number of steps.

We mentioned an electron ‘orbiting’ a hydrogen nucleus in the last paragraph deliberately,
because that is one way of thinking about an atom—as a miniature (10⁻²³ scale!) solar system
with the nucleus as the sun and the electrons as planets. This model breaks down when we
look at it in detail (as we shall see shortly), but for the moment we can use it to think about
why electrons must exist in quantized energy levels.

To do this, we need to introduce a concept from nineteenth century physics—the experi-
mentally observable fact that particles such as photons and electrons can also have the char-
acter of a wave as well as a particle. It’s not obvious why the energy of a particle should be
quantized, but it makes sense if you allow yourself to think of an electron as a wave.

Imagine a taut string—a piano wire or guitar string, for example—fixed at either end. You
may well know that such a string has a fundamental frequency: if you make it vibrate by hit-
ting or plucking it, it will vibrate in a way represented in the diagram on the right.

This diagram shows a snapshot of the string; we could also represent a ‘blurred’ image of all
the places you might find the string as it vibrates, such as you would get if you took a picture
with a slow shutter speed.

But this is not the only way the string can vibrate. An alternative possibility is shown on the
right, where not only are the ends of the string stationary, but so is the point—known as a
‘node’—right in the middle. The wavelength of the vibration in this string is half that of the
one above, so the frequency is double. Musically this vibration will sound an octave higher
and is known as the first harmonic of the first vibration we showed you, the fundamental.
Third and fourth possibilities for ‘allowed’ vibrations are shown below, and again these cor-
respond musically to further harmonics of the fundamental frequency.

Even if you have not met this idea in music or physics before, we hope that you can see that
the vibrating string has no choice but to adopt one of these quantized frequencies—the fre-
quency can take on only certain values because the fixed ends to the string means the wave-
length has to be an exact divisor of the length of the string. And as we have seen before,
frequencies are directly linked to energies: the energy levels of a vibrating string are quantized.

If you think of an electron as a wave, it becomes much easier to see why it can have only
certain energy values. If you think of an electron orbiting a nucleus as a string looped back on
itself, you can visualize from the diagrams below why only certain wavelengths are possible.
These wavelengths have associated frequencies and the frequencies have associated energies:
we have a plausible explanation for the quantization of the energy of an electron.

**Electrons occupy atomic orbitals**

The popular image of an atom as a miniature solar system, with the electrons behaving like
planets orbiting a star—the nucleus—works in some situations, but we are going to have to
leave it behind. The problem with this view of the atoms is that electrons can never be pre-
cisely located, and instead must be thought of as ‘smeared out’ over the space available to
them. The reason for this derives from Heisenberg’s Uncertainty Principle, which you can
read about in any book on quantum physics. The Uncertainty Principle tells us that we can
never know exactly both the location and the momentum of any particle. If we know the
energy of an electron (and with quantized energy levels we do), we know its momentum and
therefore we cannot know exactly where it is.

As a consequence, we have to think of electrons in atoms (and in molecules) as having a prob-
ability of being in a certain place at a certain time, and the sum of all these probabilities gives a
smeared out picture of the electron’s habits, a bit like blurred pictures of the vibrating strings.
Because an electron is free to move around an atom in three dimensions, not just two, the allowed
‘vibrations’ it can adopt are also three dimensional and are known as orbitals, or (because we are just considering electrons in a single atom for now) atomic orbitals. The shapes of these orbitals are determined by mathematical functions known as wavefunctions. The smeared out picture of the simple atomic orbital—the lowest energy state of an electron in a hydrogen atom—looks something like the picture on the left below. We have used shading to indicate the probability of finding an electron at any one point, but a more convenient way to represent an orbital is to draw a line (in reality a three-dimensional surface) encompassing the space where an electron spends, say, 95% of its time. This gives something like the picture on the right. This simplest possible orbital—the fundamental orbital of the H atom—is spherical, and is known as a 1s orbital. Higher energy atomic orbitals have different shapes, as you will see soon.

It’s useful to think of the atomic orbitals as a series of possible energy values for an electron, and to think of them as ‘occupied’ if there is an electron (or, as we shall see below, two electrons) at that energy level, and ‘unoccupied’ if there isn’t. In a hydrogen atom in its most stable state, there is only one electron, occupying the lowest energy 1s orbital. So our picture of the 1s orbital makes a good picture of what an H atom looks like too. We can also represent the 1s orbital as an energy level, and the electron which occupies it as a little arrow (which we will explain in a moment).

What happens if you put more than one electron into the orbitals around an atom? Well, for reasons we can’t go into here, each orbital can hold two electrons—and only two, never any more. If you add an electron to the H atom, you get the hydride anion, H\(^-\), which has two electrons around an H nucleus (a proton). Both of the electrons occupy the same spherical 1s orbital.

We can also represent the orbital occupancy as an energy level (the horizontal line) occupied by two electrons (the arrows). Why do we draw the electrons as arrows? Well, electrons have the property of spin, and the two electrons allowed in each orbital have to spin in opposite directions. The arrows are a reminder of these opposing spins.
The same is true for the helium atom: its two electrons occupy the same orbital. However, the energy of that orbital (and all of the other possible orbitals) will be different from the orbital for hydrogen because it has double the nuclear charge of hydrogen and the electrons are more strongly attracted to the nucleus. We can represent the orbital occupancy like this, with the energy level lower than the one for H because of this stronger attraction.

\[
\text{energy level diagram}
\]

**s and p orbitals have different shapes**

So far, so good. Now, lithium. The lowest energy 1s orbital around the Li nucleus can contain two electrons, but two only, so the third electron has to go into a higher energy orbital—one of the energy levels whose existence was inferred from atomic absorption spectroscopy. You can think of this orbital as the three-dimensional equivalent of the first harmonic of the guitar string. Like the vibration of the string, this next orbital has a node. On the string the node was the point where no motion was observed. In an atom, a node is a point where the electron can never be found—a void separating the two parts of the orbital. For the orbital containing the third electron of the Li atom, this node is spherical—it divides the orbital into two parts which nestle one within another like the layers of an onion or the stone inside a peach. We call this orbital the 2s orbital—‘2’ because we have moved up to an orbital with a node (like the first harmonic) and ‘s’ because the orbital is still spherical. The ‘s’ did not originally stand for ‘spherical’, but as all ‘s’ orbitals are spherical it’s fine to remember it that way.

\[
\text{probability distribution of electron in 2s orbital}
\]

\[
\text{schematic diagram of 2s orbital}
\]

\[
\text{conventional picture of 2s orbital (the node is not usually shown)}
\]

In a lithium atom the 1s orbital, close to the nucleus, is occupied by two electrons, while the 2s orbital, further from the nucleus, contains one. In beryllium, there is a second electron in the 2s orbital. As before the energy levels will change as the nuclear charge increases, so the orbital occupancy in Li and Be can be represented as shown below.

\[
\text{energy level diagram}
\]

When we get to boron, something a little different happens. It turns out that for an orbital with one node (such as the 2s orbital), the node does not have to be spherical. The node can
alternatively be a plane. This alternative arrangement for an orbital with a single planar node gives us a new type of orbital, the 2p orbital. A 2p orbital looks something like the picture on the left below, in ‘smeared out’ form. It is often represented as the propeller shape in the middle, and it is conventionally drawn as the shape shown in the diagram to the right.

Unlike the 1s or 2s orbitals, the 2p orbital is directional—it points along an axis, and in three dimensions there are three possible orientations for the axis, each of which gives rise to a new 2p orbital (which we can call 2px, 2py, and 2pz if we need to).

The planar node of the three 2p orbitals gives them just slightly more energy than a 2s orbital, with its spherical node. Boron atoms therefore have two electrons in the 1s orbital, two in the 2s orbital, and just one in one of the 2p orbitals. The orbital occupancy is shown in the energy level diagram on the left. You can imagine what shape each of the orbitals has: we won’t need to show a picture of them all superimposed.

The next element, carbon, with one more (a sixth) electron, seems to have a choice—it can put its sixth electron paired with the fifth one, in the same 2p orbital, or it can put it into a new 2p orbital, with both electrons unpaired. In fact it chooses the latter: electrons are negatively charged and repel one another, so if there is a choice of equal energy orbitals they occupy different orbitals singly until they are forced to start pairing up. The repulsion is never enough to force an electron to occupy a higher energy orbital, but when the orbitals are otherwise of identical energy, this is what happens.

Not surprisingly therefore, the orbitals of atoms of the remainder of the elements of the first row of the periodic table are occupied as shown below. All the while the entire set of orbitals is going down in energy because the nucleus is attracting the electrons more strongly, but otherwise it is a simple matter of filling up the 2p orbitals first singly and then doubly. With the ten electrons of neon, all the orbitals with one node are filled, and we say that neon has a ‘closed shell’. A ‘shell’ is a group of orbitals of similar energy all with the same number of nodes (in this case all called ‘2’ something—2s or 2p).
The phase of an orbital

Look at the diagrams below, which are the same as the ones on p. 83: they represent the first three vibrational frequencies of a string. Now think about the motion of the string itself: in the first vibration, all of the string moves up and down at the same time — each point on the string moves by a different amount, but the direction moved at every point is the same. The same is not true for the second ‘energy level’ of the string — during a vibration like this, the left-hand half of the string moves upwards while the right-hand half moves downwards—the two halves of the string are out of phase with one another, and there is a change of phase at the node. The same is true of the third energy level — again, there is a change of phase at each node.

The same is true for orbitals. A nodal plane, such as that in the 2p orbitals, divides the orbital into two parts with different phases, one where the phase of the wavefunction is positive and one where it is negative. The phases are usually represented by shading — one half is shaded and the other half not. You saw this in the representation of the 2p orbital above. The phase of an orbital is arbitrary, in the sense that it doesn’t matter which half you shade. It’s also important to note that phase is nothing to do with charge: both halves of a filled 2p orbital contain electron density, so both will be negatively charged.

So why is phase important? Well, in a moment we will see that, just as atoms add together to give molecules, we can add together the wavefunctions of atomic orbitals to give molecular orbitals, which tell us where electrons are, and how much energy they have, in molecules.

s, p, d, f

Why 2s, 2p…? These letters hark back to the early days of spectroscopy and refer to the appearance of certain lines in atomic emission spectra: ‘s’ for ‘sharp’ and ‘p’ for ‘principal’. Later you will meet d and f orbitals, which have other arrangements of nodes. These letters came from ‘diffuse’ and ‘fundamental’. The letters s, p, d, and f matter and you must know them, but you do not need to know what they originally stood for.

Four short clarifications about orbitals before we go on

We’re about to develop the idea of orbitals in order to understand how electrons behave in molecules, but before we go on, we should just clarify a few points about orbitals that can sometimes lead to confusion.

1. Orbitals do not need to have electrons in them — they can be vacant (there doesn’t have to be someone standing on a stair for it to exist). Helium’s two electrons fill only the 1s orbital, but an input of energy—the intense heat in the sun, for example—will make one of them hop up into the previously empty 2s, or 2p, or 3s… etc. orbitals waiting to receive them. In fact, it was observing, from earth, the energy absorbed by this process which led to the first discovery of helium in the sun.

2. Electrons may be found anywhere in an orbital except in a node. In a p orbital containing one electron, this electron may be found on either side but never in the middle. When the orbital contains two electrons, one electron doesn’t stay in one half and the other electron in the other half — both electrons could be anywhere (except in the node).

3. All these orbitals of an atom are superimposed on each other. The 1s orbital is not the middle part of the 2s orbital. The 1s and 2s orbitals are separate orbitals in their own rights and each can hold a maximum of two electrons but the 2s orbital does occupy some of the same space as the 1s orbital (and also as the 2p orbitals, come to that). Neon, for example, has ten electrons in total: two will be in the 1s orbital, two in the
(much bigger) 2s orbital, and two in each of the three 2p orbitals. All these orbitals are superimposed on each other.

4. As we move across subsequent rows of the periodic table—starting with sodium—the 1s, 2s, and 2p orbitals are already filled with electrons, so we must start putting electrons into the 3s and 3p orbitals, then the 4s, 3d, and 4p orbitals. With d orbitals (and f orbitals, which start to be filled in the lanthanide series) there are yet further new arrangements of nodes. We won’t be discussing these orbitals in detail—you will find detailed consideration in an inorganic textbook—but the principles are just the same as the simple arrangements we have described.

Molecular orbitals—diatomic molecules

Now for electrons in molecules. Just as the behaviour of electrons in atoms is dictated by the atomic orbitals they reside in, so electrons in molecules behave in ways dictated by the molecular orbitals which contain them. We think of molecules as being built from atoms (even if that is not actually how you would usually make them), and likewise we can think of molecular orbitals as being built up from a combination of atomic orbitals.

As atomic orbitals are wavefunctions, they can be combined in the same way that waves combine. You may be already familiar with the ideas of combining waves either constructively (in phase) or destructively (out of phase):

Diagram showing constructive and destructive overlap of atomic orbitals.

Atomic orbitals can combine in the same ways—in phase or out of phase. Using two 1s orbitals drawn as circles (representing spheres) with dots to mark the nuclei and shading to represent phase, we can combine them in phase (that is, we add them together), resulting in an orbital spread over both atoms, or out of phase (by subtracting one from the other). In this case we get a molecular orbital with a nodal plane down the centre between the two nuclei, where the wavefunctions of the two atomic orbitals exactly cancel one another out and with two regions of opposite phase.

Diagram showing the combination of 1s orbitals to form a bonding and an antibonding molecular orbital.

The resulting orbitals belong to both atoms—they are molecular rather than atomic orbitals. Now, imagine putting electrons into the first of these orbitals (the bonding orbital). Remember, you can put zero, one, or two electrons into an orbital, but no more. The diagram of the orbital shows that the electrons would spend most of their time in between the two atomic nuclei. Being negatively charged, the electrons will exert an attractive force on each of the nuclei, and would hold them together. We have a chemical bond! For this reason the in-phase molecular orbital is called a bonding orbital.
The out-of-phase molecular orbital offers no such attractive possibility—in fact putting electrons into the out-of-phase molecular orbital works against bonding. These electrons are mainly to be found anywhere *but* between the two nuclei, where there is a node. The exposed positively charged nuclei repel each other, and that is why this orbital is known as an **anti-bonding molecular orbital**.

The combination of the atomic 1s orbitals to give the two new molecular orbitals can also be shown on a molecular orbital energy level diagram. The two atomic orbitals are shown on the left and the right, and the molecular orbitals which result from combining them in and out of phase are shown in the middle. The diagram as a whole is a sort of ‘before and after’ diagram—the situation before the interaction between the orbitals is shown on the left and the right, and after the interaction is shown in the middle. Notice that the bonding orbital is lower in energy than the constituent 1s orbitals, and the antibonding orbital is higher.

Now we can actually put the electrons into the orbitals, just as we did on p. 84 when we were building up the picture of atomic orbitals. Each hydrogen atom has one electron and so the resulting hydrogen molecule (shown in the middle) contains two electrons. Always fill up orbitals from the lowest energy first, putting a maximum of two electrons into each orbital, so both of these electrons go into the bonding orbital. The antibonding orbital remains empty. The electrons therefore spend most of their time in between the nuclei, and we have a plausible explanation for the existence of a chemical bond in the H₂ molecule.

Diagrams such as these are central to the way we can use molecular orbital theory (MO theory) to explain structure and reactivity, and you will in future meet many more of them. So before we go on it is worth clarifying several points about this one:

- **Two** atomic orbitals (AOs) combine to give **two** molecular orbitals (MOs). You always get the same number of MOs out as you put AOs in.
- Adding the wavefunctions (combining them in phase) of the two AOs makes the bonding orbital; subtracting them (combining them out of phase) makes the antibonding orbital.
• Since the two atoms are the same (both H), each AO contributes the same amount to the MOs (this will not always be the case).
• The bonding MO is lower in energy than the AOs.
• The antibonding MO is higher in energy than the AOs.
• Each hydrogen atom initially had one electron. The spin of these electrons is unimportant.
• The two electrons end up in the MO lowest in energy—the bonding MO.
• Just as with AOs, each MO can hold two electrons as long as the electrons are spin-paired (shown by opposing arrows). You do not need to be concerned with the details of spin-pairing at this stage, just with the result that any orbital may contain no more than two electrons.
• The two electrons between the two nuclei in the bonding MO hold the molecule together—they are the chemical bond.
• Since these two electrons are lower in energy in the MO than they were in the AOs, the molecule is more stable than its constituent atoms; energy is given out when the atoms combine.
• Or, if you prefer, we must put in energy to separate the two atoms again and to break the bond.

From now on, we will always represent molecular orbitals in energy order—the highest-energy MO at the top (usually an antibonding MO) and the lowest in energy (usually a bonding MO and the one in which the electrons are most stable) at the bottom.

Before you leave this section, let’s recap how we got to the MO diagram of H₂. It’s worth working through these steps to check you can draw your own MO diagram before you leave this section.

1. Draw two H atoms along with the 1s atomic orbitals which contain the electron, one on either side of the page.
2. Sketch the result of adding and of subtracting the wavefunctions of these two 1s orbitals to show the bonding and antibonding MOs. These go one above the other (high energy antibonding orbital on top) in between the AOs.
3. Count up the total number of electrons in the atoms going in to the molecule, and put that number of electrons into the MOs, starting at the bottom and building upwards, two in each orbital.

Breaking bonds

The diagram we have studied shows the most stable ground state of a hydrogen molecule, in which the electrons have the lowest possible energy. But what happens if an electron is promoted up from the lowest energy level, the bonding MO, to the next lowest energy level, the antibonding MO? Again, an energy level diagram helps.
Now the electron in the antibonding orbital cancels out the bonding of the electron in the bonding orbital. Since there is no overall bonding holding the two atoms together, they can drift apart as two separate atoms with their electrons in 1s AOs. In other words, promoting an electron from the bonding MO to the antibonding MO breaks the chemical bond. This is difficult to do with hydrogen molecules but easy with, say, bromine molecules. Shining light on Br₂ causes it to break up into bromine atoms.

**Why hydrogen is diatomic but helium is not**

Like H atoms, He atoms have their electrons in 1s orbitals, so we can construct an energy level diagram for He₂ in a similar way. But there is one big difference: each helium atom has two electrons so now both the bonding MO and the antibonding MO are full! Any bonding due to the electrons in the bonding orbital is cancelled out by the electrons in the antibonding orbital, and the He₂ molecule falls apart. He₂ does not exist.

![Diagram of He₂ molecule](image)

**Bond order**

Only if there are more electrons in bonding MOs than in antibonding MOs will there be any bonding between two atoms. In fact, we define the number of bonds between two atoms as the bond order (dividing by two since two electrons make up a chemical bond).

\[
\text{bond order} = \frac{(\text{no. of electrons in bonding MOs}) - (\text{no. of electrons in antibonding MOs})}{2}
\]

Hence the bond orders for H₂ and He₂ are

\[
\text{bond order (H₂)} = \frac{2 - 0}{2} = 1, \text{ i.e. a single bond}
\]

\[
\text{bond order (He₂)} = \frac{2 - 2}{2} = 0, \text{ i.e. no bond}
\]

**Forming bonds using 2s and 2p atomic orbitals: σ and π orbitals**

Atoms in the row of the periodic table running from Li to F have electrons in 2s and 2p orbitals, and as all molecules of interest to organic chemists contain at least one such atom we now need to think about how 2s and 2p orbitals interact. We also need to introduce you to a useful piece of terminology that is used to describe the *symmetry* of molecular orbitals.

We can do all of this by thinking about the bonding in another ubiquitous diatomic gas, N₂. N atoms have electrons in 1s, 2s, and 2p orbitals, so we need to consider interactions between pairs of each of these orbitals in turn.
1s orbitals we have already dealt with. Combining 2s orbitals is essentially just the same; they form bonding and antibonding orbitals just as 1s orbitals do and with similar shapes too, but higher energies, because the 2s orbitals are higher in energy than the 1s orbitals. The 2s orbitals are also bigger than 1s orbitals, and because of their ‘onion skin’ form, the exact nature of the MOs they give rise to is more complex than those which come from 1s AOs, but you can represent them in sketches in just the same way:

The bonding orbitals formed from 1s–1s and 2s–2s interactions have another important feature in common: they are all cylindrically symmetrical. In other words, if you look at the molecular orbital end-on, you can rotate it around the axis between the two atoms by any amount and it looks identical. It has the symmetry of a cigar, a carrot, or a baseball bat. Bonding orbitals with cylindrical symmetry like this are known as σ (sigma) orbitals, and the bonds which result from putting two electrons into these orbitals are known as σ bonds. The single bond in the H₂ molecule is therefore a σ bond.

The antibonding orbitals which result from combining these AOs are also cylindrically symmetrical and are called σ* orbitals, with the * denoting their antibonding character.

Now for the 2p orbitals. As described on p. 86 each atom has three mutually perpendicular 2p atomic orbitals. In a diatomic molecule, such as N₂, these 2p orbitals must combine in two different ways—one p orbital from each atom (shown in red here) can overlap end-on, but the other two p orbitals on each atom (shown in black) must combine side-on.

We’ll deal with the end-on overlap first. This is what happens if we combine the two 2p orbitals out of phase: as with the 2s orbitals, we have a node between the atoms, and any electron in this MO would spend most of its time not between the nuclei—as you can guess, this is an antibonding orbital.
If we combine the orbitals in phase, this is what we get.

![Diagram of bonding σ molecular orbital]

There is a nice rich area of electron density between the nuclei, and somewhat less outside, so overall filling this orbital with electrons would lead to an attraction between the atoms and a bond would result.

Both of these MOs have cylindrical symmetry and are therefore designated σ and σ* orbitals, and a bond formed by filling the MO made from interacting two 2p orbitals end-on is called a σ bond.

- σ bonds can be made from s or p atomic orbitals, provided they form a cylindrically symmetrical molecular orbital.

Each atom presents its other two 2p orbitals for side-on overlap. This is what the antibonding MO formed by out-of-phase combination of two side-on p orbitals looks like:

![Diagram of antibonding π* molecular orbital]

And this is the bonding, in-phase combination

![Diagram of bonding π molecular orbital]

These MOs do not have cylindrical symmetry—in fact you have to rotate them 180° about the axis between the nuclei before you get back something looking like what you started with but with opposite phase—and as a result the symmetry of these orbitals is given the symbol π: the bonding orbital is a π orbital and the antibonding orbital is a π* orbital. Bonds which are formed by filling π orbitals are called π bonds, and you’ll notice that because of the π symmetry the electron density in these bonds does not lie directly between the two nuclei but rather to either side of the line joining them.

Since an atom has three mutually perpendicular 2p orbitals, two of which can interact side-on in this way, there will exist a pair of degenerate (equal in energy) mutually perpendicular π orbitals and likewise a pair of degenerate mutually perpendicular π* orbitals. (The third p orbital interacts end-on, forming a σ orbital and a σ* orbital, of course).

The two sorts of MOs arising from the combinations of the p orbitals are, however, not degenerate—more overlap is possible when the AOs overlap end-on than when they overlap side-on. As a result, the 2p–2p σ orbital is lower in energy than the 2p–2p π orbitals.

We can now draw an energy level diagram to show the combinations of the 1s, 2s, and 2p AOs to form MOs, labelling each of the energy levels with σ, σ*, π, or π* as appropriate.

Because it can be difficult to represent exactly the result of adding and subtracting p orbitals, you will often see π and π* orbitals represented in diagrams simply as their ‘uncombined’ p orbitals—the structures on the left above. For an example, see p. 105.
Now for the electrons. Each nitrogen atom contributes seven electrons to the molecule, so we have to fill this stack of orbitals with 14 electrons, starting at the bottom. The result is:

The $\sigma$ and $\sigma^*$ MOs formed from interactions between the two 1s orbitals, and the two 2s orbitals are all filled: no overall bonding results because the filled bonding and antibonding orbitals cancel each other out. All the bonding is done with the remaining six electrons. They fit neatly into a $\sigma$ bond from two of the $p$ orbitals and two $\pi$ bonds from the other two pairs.
The electrons in the $\sigma$ bond lie between the two nuclei, while the electrons in the two $\pi$ bonds lie in two perpendicular clouds flanking the central $\sigma$ bond.

Calculating the bond order in $\text{N}_2$ is easy—a total of ten bonding electrons and four anti-bonding electrons gives a credit of six, or a bond order of three. $\text{N}_2$ has a triple-bonded structure.

We can’t, however, ignore the electrons that are not involved in bonding: there are eight of them altogether. These non-bonding electrons can be thought of as being localized on each of the N atoms. The four 1s electrons are low-energy inner shell electrons that are not involved in the chemistry of $\text{N}_2$, while the four 2s electrons provide the non-bonded lone pairs located one on each N atom. In the structure shown here we have drawn them in: you don’t have to draw lone pairs of every molecule that has them, but sometimes it can be useful to emphasize them—for example if they are taking part in a reaction scheme.

**Bonds between different atoms**

Up to now we have only considered combining two atoms of the same element, which makes things simpler because the same orbitals on each of the two atoms have the same energy. But when the two atoms are different two things change. The first is obvious—the number of electrons contributed by each atom is different. This is easy to accommodate since it just affects the total number of electrons we need to put into the MO diagram when we fill up the energy levels. So, for example, if you were constructing an MO diagram for $\text{NO}$, the gas nitric oxide (NO, a rather remarkable biological messenger in the human body) rather than $\text{N}_2$, you simply put in a total of 15 rather than 14 electrons because O contributes eight electrons and N seven.

**Nitric oxide, NO**

Nitric oxide was for a long time known only as one of the villains of urban air pollution, being formed during the combustion of petroleum and other fossil fuels. In the last 20 years, however, it has become evident that it is much more than that—one unexpected role, which earned its discoverers the Nobel Prize in physiology in 1998, is as a biological messenger, managing the contraction of smooth vessels and hence regulating blood flow.

The second thing that changes when you have two different atoms bonded together is the relative energies of the AOs being combined. It may seem natural to assume that a 2p orbital has the same energy whatever atom it finds itself in, but of course the difference is that an electron in a 2p (or any other) orbital feels an attraction to the nucleus which depends on the nuclear charge. The greater the number of protons in the nucleus, the greater the attraction, and hence the more tightly held, more stable, and lower in energy the electron becomes.

This is the origin of electronegativity. The more electronegative an atom is, the more it attracts electrons, the lower in energy are its AOs, and so any electrons in them are held more tightly.
As you move across each row of the periodic table, therefore, electronegativity increases as the energy of each orbital drops. From Li (electronegativity 0.98) across to C (2.55), and on to N (3.04), O (3.44), and F (3.98), the elements steadily become more electronegative and the AOs lower in energy.

So our diagram of the orbitals of NO actually looks like this.

---

We have shown only the 2s and 2p orbitals as the 1s orbitals are much lower in energy, and as you saw in the diagram of N₂ on p. 94 their bonding and antibonding interactions cancel each other out.

The orbitals on O are lower in energy than the orbitals on N, but they still interact just fine. However, there is one interesting consequence: if you look at each bonding orbital, you will see that it is closer in energy to the contributing orbital on O than the contributing orbital on N. Likewise, each antibonding orbital is closer in energy to the contributing orbital on N than the contributing orbital on O. The result is that the MOs are unsymmetrical, and while all the bonding orbitals have a greater contribution from the oxygen AOs, all the antibonding orbitals have a greater contribution from the nitrogen AOs. Overall the diagram shows eight electrons in bonding orbitals and three electrons in antibonding orbitals, so the overall electron distribution is skewed (polarized) towards O, just as you would expect from a comparison of the electronegativities of N and O.

The eight electrons in bonding orbitals and three electrons in antibonding orbitals means that NO has a bond order of 2½. It also has an unpaired electron—it is a radical. We can’t easily represent half a bond in valence bond terms, so we usually draw NO with a double bond, representing four bonding electrons. The remaining seven electrons can be shown as three lone pairs and one unpaired electron. Where do we put them? Well, our MO diagram tells us that the unpaired electron occupies an orbital closer in energy to N than to O, so we put that on N.

N and O differ only slightly in electronegativity (electronegativity of N 3.04; O 3.44): their orbitals are quite close in energy and form stable covalent bonds. But we also need to consider what happens when two atoms forming a bond differ hugely in electronegativity. We can take sodium (electronegativity 0.93) and chlorine (electronegativity 3.16) as our example. We know from observation that the product of reacting these two elements (don’t try this at home) is the ionic solid Na⁺ Cl⁻, and the MO energy level diagram tells us why.

The AOs we need to consider are the 3s and 3p orbitals of Na (all its lower energy 1s, 2s, and 2p orbitals are filled, so we can ignore those, as we did with the 1s orbitals of N₂ and NO above) and the 3s and 3p orbitals of Cl (again, the 1s, 2s, and 2p orbitals are all filled). Here is the diagram, with the Na orbitals much higher in energy than the Cl orbitals.
Trying to construct a molecular orbital diagram for NaCl

But these AOs are too far apart in energy to combine to form new MOs and no covalent bond is formed. The orbitals which get filled are simply the 3s and 3p orbitals of the Cl atom. The electrons available to fill these orbitals are the seven provided by Cl plus the one from Na: we end up with Na⁺ and Cl⁻. The ionic bonding in NaCl is due simply to the attraction between two oppositely charged ions—there is no orbital overlap.

These three different cases where the two combining orbitals differ greatly in energy, only a little, or not at all are summarized below.

<table>

<td></td>
<td></td>
</tr>
</tbody>
</table>

These three cases are summarized below.

- **Energies of AOs both the same**:
  - Large interaction between AOs
  - Bonding MO much lower in energy than AOs
  - Antibonding MO is much higher in energy than the AOs
  - Both AOs contribute equally to the MOs
  - Electrons in bonding MO are shared equally between the two atoms
  - Bond between A and B would classically be described as purely covalent
  - Easiest to break bond into two radicals (homolytic fission)
  - Heterolytic fission of the bond is possible and could give either A⁺ and B⁻ or A⁻ and B⁺

- **AO on atom B is a little lower in energy than AO on atom A**:
  - Less interaction between AOs
  - Bonding MO is lowered by a small amount relative to AO on atom B
  - Antibonding MO is raised in energy by a small amount relative to AO on atom A
  - The AO on B contributes more to the bonding MO and the AO on A contributes more to the antibonding MO
  - Electrons in bonding MO are shared between atoms but are associated more with B than A
  - Bond between A and B is covalent but there is also some electrostatic (ionic) attraction between atoms
  - Easiest to break bond into two ions, A⁺ and B⁻, although it is also possible to give two radicals

- **AO on atom B is a lot lower in energy than AO on atom A**:
  - AOs are too far apart in energy to interact
  - The filled orbital on the same energy as the AO on atom B
  - The empty orbital on the cation has the same energy as the AO on atom A
  - Only one AO contributes to each MO
  - Electrons in the filled orbital are located only on atom B
  - Bond between A and B is covalent but there is also some electrostatic (ionic) attraction between atoms
  - Easiest to break bond into two ions, A⁻ and B⁺, although it is also possible to give two radicals
  - Compound already exists as ions A⁻ and B⁺
Other factors affecting degree of orbital interaction

Having similar energies is not the only criterion for good interaction between two AOs. It also matters how the orbitals overlap. We have seen that p orbitals overlap better in an end-on fashion (forming a σ bond) than they do side-on (forming a π bond). Another factor is the size of the AOs. For best overlap, the orbitals should be the same size—a 2p orbital overlaps much better with another 2p orbital than it does with a 3p or 4p orbital.

A third factor is the symmetry of the orbitals—two AOs must have the appropriate symmetry to combine. Thus a 2pₓ orbital cannot combine with a 2pᵧ or 2pₜ orbital since they are all perpendicular to each other (they are orthogonal). Depending on the alignment, there is either no overlap at all or any constructive overlap is cancelled out by equal amounts of destructive overlap. Likewise, an s orbital can overlap with a p orbital only end-on. Sideways overlap leads to equal amounts of bonding and antibonding interactions and no overall gain in energy.

Molecular orbitals of molecules with more than two atoms

We now need to look at ways of combining more than two atoms at a time. For some molecules, such as H₂S and PH₃, which have all bond angles equal to 90°, the bonding should be straightforward—the 3p orbitals (which are at 90°) on the central atom simply overlap with the 1s orbitals of the hydrogen atoms.

Now, you might imagine it would be similar for ammonia, NH₃, since N lies above P in the periodic table. The trouble is, we know experimentally that the bond angles in ammonia, as in water and methane, are not 90°, but instead 104°, 107°, and 109°, respectively. All the covalent compounds of elements in the row Li to Ne raise this difficulty. How can we get 109° angles from orbitals arranged 90° apart?

To see what has to happen, we’ll start with a molecule of methane enclosed in a cube. It is possible to do this since the opposite corners of a cube describe a perfect tetrahedron. The carbon atom is at the centre of the cube and the four hydrogen atoms are at four of the corners.

Now let’s consider each of the carbon’s 2s and 2p AOs in turn. The carbon’s 2s orbital can overlap with all four hydrogen 1s orbitals at once with all the orbitals in the same phase.
Each of the 2p orbitals points to a pair of opposite faces of the cube. Once more all four hydrogen 1s orbitals can combine with each p orbital, provided the hydrogen AOs on the opposite faces of the cube are of opposite phases.

The three MOs generated in this way are degenerate, and this gives us four bonding orbitals. Along with four associated antibonding orbitals this gives us a total of eight MOs, which is correct since there were eight AOs (C gave us 2s and 3 × 2p, while 4 × H gave us 4 × 1s).

Using this approach, it is possible to construct a complete MO picture of methane—and indeed for very much more complex molecules than methane. There is experimental evidence too that these pictures are correct. But the problem is this: the four filled, bonding orbitals of methane are not all the same (one came from the interaction with the C 2s orbital and three from the C 2p orbitals). But we also know from experimental observations all four C–H bonds in methane are the same.

Something seems to be wrong, but there is in fact no contradiction. The MO approach tells us that there is one MO of one kind and three of another but the electrons in them are shared out over all five atoms. No one hydrogen atom has more or fewer electrons than any other—they are all equivalent. Techniques that tell us the structure of methane do not tell us where bonds are; they simply tell us where the atoms are located in space—we draw in bonds connecting atoms together. Certainly the atoms form a regular tetrahedron but exactly where the electrons are is a different matter entirely. So, do we have to give up the idea that methane has four bonds, each made of two electrons, linking the C with an H? If we choose to, then for every reaction, even of the simplest molecules, we are going to need to calculate, by computer, a full set of MOs and all of their interactions.

That would be using physics to do chemistry. It might be accurate but it would kill creativity and invention. So here is an alternative: we keep our tried and tested practical picture of molecules made from discrete bonds, each containing a pair of electrons, but we make it compatible with MO theory. To do this we need a concept known as hybridization.

**Hybridization of atomic orbitals**

To get a picture of methane with four equivalent pairs of electrons we need to start with four equivalent AOs on C, which we don’t have. But we can get them if we combine the carbon 2s and 2p orbitals first to make four new orbitals, each composed of one-quarter of the 2s orbital and three-quarters of one of the p orbitals. The new orbitals are called sp³ (that’s said s-p-three, not s-p-cubed) hybrid orbitals to show the proportions of the AOs in each. This process of mixing is called hybridization. The hybrid orbitals are mathematically equivalent to the 2s and 2p orbitals we started with, and they have the advantage that when we use them to make MOs the orbitals correspond to bonding pairs of electrons.
What do the four hybrid orbitals look like? Each sp\(^3\) orbital takes three-quarters of its character from a p orbital and one-quarter from an s orbital. It has a planar node through the nucleus like a p orbital but one lobe is larger than the other because of the extra contribution of the 2s orbital: the symmetry of the 2s orbital means that adding it to a 2p orbital will increase the size of the wavefunction in one lobe, but decrease it in the other.

The four sp\(^3\) orbitals point to the corners of a tetrahedron and we build up a molecule of methane by overlapping the large lobe of each sp\(^3\) orbital with the 1s orbital of a hydrogen atom, as shown in the margin. Each overlap forms an MO (2sp\(^3\) + 1s) and we can put two electrons in each to form a C–H σ bond. There will of course also be an antibonding MO, σ* (2sp\(^3\) – 1s) in each case, but these orbitals are empty. Overall, the electrons are spatially distributed exactly as they were in our previous model, but now we can think of them as being located in four bonds.

The great advantage of this method is that it can be used to build up structures of much larger molecules quickly and without having to imagine that the molecule is made up from isolated atoms. Take ethane, for example. Each carbon uses three sp\(^3\) AOs orientated towards the three hydrogen atoms, leaving one sp\(^3\) orbital on each carbon atom for the C–C bond.

In the MO energy level diagram we now have both C–H bonding σ and antibonding σ* orbitals (made from combining sp\(^3\) orbitals on C with 1s orbitals on H) and also a C–C bonding σ and antibonding σ* orbital, made from two sp\(^3\) orbitals on C. The diagram below just shows the C–C bond.

For ethene (ethylene), the simplest alkene, we need a new set of hybrid orbitals. Ethene is a planar molecule with bond angles close to 120°. Our approach will be to hybridize all the
orbits needed for the C–H framework and see what is left over. In this case we need three equivalent bonds from each carbon atom (one to make a C–C bond and two to make C–H bonds). Therefore we need to combine the 2s orbital on each carbon atom with two p orbitals to make the three bonds. We could hybridize the 2s, 2pₓ, and 2pᵧ orbitals (that is, all the AOs in the plane) to form three equal sp² orbitals, leaving the 2pₓ orbital unchanged. These sp² hybrid orbitals will have one-third s character and only two-thirds p character.

The three sp² hybrid AOs on each carbon atom can overlap with three other orbitals (two hydrogen 1s AOs and one sp² AO from the other carbon) to form three σ MOs. This leaves the two 2pₓ orbitals, one on each carbon, which combine to form the π MO. The skeleton of the molecule has five σ bonds (one C–C and four C–H) in the plane and the central π bond is formed by two 2pₓ orbitals above and below the plane.

This is the first MO picture we have constructed with a C= C double bond, and it is worth taking the time to think about the energies of the orbitals involved. We’ll again ignore the C–H bonds, which involve two of the sp² orbitals of each C atom. Remember, we mixed two of the three 2p orbitals in with the 2s orbital to make 3 × sp² orbitals on each C atom, leaving behind one unhybridized 2p orbital.

Now, first we need to generate the σ and σ* orbitals by interacting one sp² orbital on each atom. Then we need to deal with the two p orbitals, one on each C, which interact side-on. The unhybridized p orbitals are a bit higher in energy than the sp² orbitals, but they interact less well (we discussed this on p. 93) so they give a π orbital and a π* orbital whose energies are in between the σ and σ* orbitals. Each C atom donates two electrons to these orbitals (the other two electrons are involved in the two bonds to H), so the overall picture looks like this. Two AOs give two MOs.
The fact that the sideways overlap of the p orbitals to form a $\pi$ bond is not as effective as the head-on overlap of the orbitals to form a $\sigma$ bond means that it takes less energy to break a C–C $\pi$ bond than a C–C $\sigma$ bond (about 260 kJ mol$^{-1}$ compared to about 350 kJ mol$^{-1}$).

Ethyne (acetylene) has a C≡C triple bond. Each carbon bonds to only two other atoms to form a linear CH skeleton. Only the carbon 2s and 2px have the right symmetry to bond to the two atoms at once so we can hybridize these to form two sp hybrids on each carbon atom, leaving the 2py and 2pz to form $\pi$ MOs with the 2p orbitals on the other carbon atom. These sp hybrids have 50% each s and p character and form a linear carbon skeleton.

We could then form the MOs as shown below. Each sp hybrid AO overlaps with either a hydrogen 1s AO or with the sp orbital from the other carbon. The two sets of p orbitals combine to give two mutually perpendicular $\pi$ MOs.

Hydrocarbon skeletons are built up from tetrahedral (sp$^3$), trigonal planar (sp$^2$), or linear (sp) hybridized carbon atoms. Deciding what sort of hybridization any carbon atom has, and hence what sort of orbitals it will use to make bonds, is easy. All you have to do is count up the atoms bonded to each carbon atom. If there are two, that carbon atom is linear (sp hybridized), if there are three, that carbon atom is trigonal (sp$^2$ hybridized), and if there are four, that carbon atom is tetrahedral (sp$^3$ hybridized). Since the remaining unhybridized p orbitals are used to make the $\pi$ orbitals of double or triple bonds, you can also work out hybridization state just by counting up the number of $\pi$ bonds at each carbon. Carbon atoms with no $\pi$ bonds are tetrahedral (sp$^3$ hybridized), those with one $\pi$ bond are trigonal (sp$^2$ hybridized), and those with two $\pi$ bonds are linear (sp hybridized).

There’s a representative example on the left. This hydrocarbon (hex-5-en-2-yne) has two linear sp carbon atoms (C2 and C3), two trigonal sp$^2$ carbon atoms (C5 and C6), a tetrahedral sp$^3$ CH$_2$ group in the middle of the chain (C4), and a tetrahedral sp$^3$ methyl group (C1) at the end of the chain. We had no need to look at any AOs to deduce this—we needed only to count the bonds.

**We can hybridize any atoms**

We can use the same ideas with any sort of atom. The three molecules shown on the next page all have a tetrahedral structure, with four equivalent $\sigma$ bonds from the central tetrahedral sp$^3$
atom, whether this is B, C, or N, and the same total number of bonding electrons—the molecules are said to be isoelectronic. The atoms contribute different numbers of electrons so to get the eight bonding electrons we need we have to add one to BH₄ and subtract one from NH₃—hence the charges in BH₄ and NH₃⁺. In each case the central atom can be considered to be sp³ hybridized, using an sp³ orbital to bond to each of the four H atoms, each resulting σ bond being made up of two electrons.

Compounds of the same three elements with only three bonds take more thinking about. Borane, BH₃, has only three pairs of bonding electrons (three from B and three from the three H atoms). Since the central boron atom bonds to only three other atoms we can therefore describe it as being sp² hybridized. Each of the B–H bonds results from the overlap of an sp² orbital with the hydrogen 1s orbital. Its remaining p orbital is not involved in bonding and must remain empty. Do not be tempted by the alternative structure with tetrahedral boron and an empty sp³ orbital. You want to populate the lowest energy orbitals for greatest stability and sp³ orbitals with their greater s character are lower in energy than sp² orbitals. Another way to put this is that, if you have to have an empty orbital, it is better to have one with the highest possible energy since it has no electrons in it and so it doesn’t affect the stability of the molecule.

Borane is isoelectronic with the methyl cation, CH₃⁺ or Me⁺. All the arguments we have just applied to borane also apply to Me⁺ so it too is sp² hybridized with a vacant p orbital. This will be very important when we discuss the reactions of carbocations in Chapters 15 and 36.

Now what about ammonia, NH₃? Ammonia is not isoelectronic with borane and Me⁺! It has a total of eight electrons—five from N and three from 3 × H. As well as three N–H bonds, each with two electrons, the central nitrogen atom also has a lone pair of electrons. We have a choice: either we could hybridize the nitrogen atom sp² and put the lone pair in the p orbital or we could hybridize the nitrogen sp³ and have the lone pair in an sp³ orbital.

This is the opposite of the situation with borane and Me⁺. The extra pair of electrons does contribute to the energy of ammonia so it prefers to be in the lower-energy orbital, sp³, rather than pure p. Experimentally the H–N–H bond angles are all 107.3°. Clearly, this is much closer to the 109.5° sp³ angle than the 120° sp² angle. But the bond angles are not exactly 109.5°, so ammonia cannot be described as pure sp³ hybridized. One way of looking at this is to say that the lone pair repels the bonds more than they repel each other. Alternatively, you could say that the orbital containing the lone pair must have slightly more s character while the N–H bonding orbitals must have correspondingly more p character.

The carbonyl group

The C=O double bond is the most important functional group in organic chemistry. It is present in aldehydes, ketones, acids, esters, amides, and so on. We shall spend several chapters discussing its chemistry so it is important that you understand its electronic structure from this early stage. We’ll use the simplest carbonyl compound, methanal (formaldehyde), as our example. As in alkenes, the carbon atom needs three sp² orbitals to form σ bonds with the two H atoms and the O atom. But what about oxygen? It needs only to form one σ bond to C, but it needs two more hybrid orbitals for its lone pairs: the oxygen atom of a carbonyl group is also sp² hybridized. A p orbital from the carbon and one from the oxygen make up the π bond, which also contains two electrons. This is what the bonding looks like:

How do we know the O has its lone pairs in sp² orbitals? Well, whenever carbonyl compounds form bonds using those lone pairs—hydrogen bonds, for example—they prefer to do so in a direction corresponding to where the lone pairs are expected to be.
For the MO energy diagram, we’ll again just consider the bonding between C and O. First, we hybridize the orbitals of both atoms to give us the $3 \times sp^2$ orbitals and $1 \times p$ orbital we need. Notice that we have made the AOs at O lower in energy than the AOs at C because O is more electronegative. Once we have accounted for the non-bonding $sp^2$ orbitals at O and the two C–H bonds, we allow the two remaining $sp^2$ orbitals to interact and make a $\sigma$ and a $\sigma^*$ orbital, and the two $p$ orbitals to make a $\pi$ and a $\pi^*$ orbital.

The fact that oxygen is more electronegative than carbon has two consequences for this diagram. Firstly, it makes the energy of the orbitals of a C=O bond lower than they would be in the corresponding C=C bond. That has consequences for the reactivity of alkenes and carbonyl compounds, as you will see in the next chapter.

The second consequence is polarization. You met this idea before when we were looking at NO. Look at the filled $\pi$ orbital in the MO energy level diagram. It is more similar in energy to the $p$ orbital on O than the $p$ orbital on C. We can interpret this by saying that it receives a greater contribution from the $p$ orbital on O than from the $p$ orbital on C. Consequently, the orbital is distorted so that it is bigger at the O end than at the C end, and the electrons spend more time close to O. The same is true for the $\sigma$ bond, and the consequent polarization of the C=O group can be represented by one of two symbols for a dipole—the arrow with the cross at the positive end or the pair of $\delta^+$ and $\delta^-$ symbols.

Conversely, if you look at the antibonding $\pi^*$ orbital, it is closer in energy to the $p$ orbital on C than the $p$ orbital on O and therefore it receives a greater contribution from the $p$ orbital on C. It is distorted towards the carbon end of the bond. Of course, being empty, the $\pi^*$ orbital has no effect on the structure of the C=O bond. However, it does have an effect on its reactivity—it is easier to put electrons into the antibonding $\pi^*$ orbital at the C end than at the O end.
Rotation and rigidity

To end this chapter, we deal with one more question which MOs allow us to answer: how flexible is a molecule? The answer depends on the molecule of course, but more importantly it depends on the type of bond. You may be aware that many alkenes can exist in two forms, cis and trans, also called Z and E (see Chapter 17). These two forms are not usually easy to interconvert—in other words the C=C double bond is very rigid and cannot rotate.

If we look at the bonding in but-2-ene we can see why. The π bond is made up of two parallel p orbitals. To rotate about the π bond requires those orbitals to lose their interaction, pass through a state in which they lie perpendicular, and finally line up again. That transitional, perpendicular state is very unfavourable because all of the energy gained through π bonding is lost. Alkenes are rigid and do not rotate.

Alkenes are rigid...

![Diagram of Alkenes]

It is in fact possible to interconvert cis and trans alkenes, but it requires a considerable amount of energy—around 260 kJ mol⁻¹. One way to break the π bond is to promote an electron from the π orbital to the π* orbital. If this were to happen, there would be one electron in the bonding π orbital and one in the antibonding π* orbital, and hence no overall bonding. The energy required to do this corresponds to light in the ultraviolet (UV) region of the spectrum. Shining UV light on an alkene can break the π bond (but not the σ bond) and allows rotation to occur.

Alkene isomers

Maleic and fumaric acids were known in the nineteenth century to have the same chemical composition and the same functional groups, and yet they were different compounds—why remained a mystery. That is, until 1874 when van’t Hoff proposed that free rotation about double bonds was restricted. This meant that, whenever each carbon atom of a double bond had two different substituents, isomers would be possible. He proposed the terms cis (Latin meaning ‘on this side’) and trans (Latin meaning ‘across or on the other side’) for the two isomers. The problem was: which isomer was which?

On heating, maleic acid readily loses water to become maleic anhydride so this isomer must have both acid groups on the same side of the double bond.

![Diagram of Maleic and Fumaric Acids]

Compare that situation with butane. Rotating about the middle bond doesn’t break any bonds because the σ bond is, by definition, cylindrically symmetrical. Atoms connected only by a σ bond are therefore considered to be rotationally free, and the two ends of butane can spin relative to one another.

Alkanes rotate freely...

The same comparison works for ethylene (ethene) and ethane: in ethylene all the atoms lie in a plane, enforced by the need for overlap between the p orbitals. But in ethane, the two ends of the molecule spin freely. This difference in rigidity has important consequences throughout chemistry, and we will come back to it in more detail in Chapter 16.
Conclusion

We have barely touched the enormous variety of molecules, but it is important that you realize at this point that these simple ideas of structural assembly can be applied to the most complicated molecules known. We can use AOs and combine them into MOs to solve the structure of very small molecules and to deduce the structures of small parts of much larger molecules. With the additional concept of conjugation in Chapter 7 you will be able to grasp the structure of any organic compound. From now on we shall use terms like AO and MO, 2p orbital, sp² hybridization, σ bond, energy level, and populated orbital without further explanation. If you are unsure about any of them, refer back to this chapter.

Looking forward

We started the chapter with atomic orbitals, which we combined into molecular orbitals. But what happens when the orbitals of two molecules interact? This is what happens during chemical reactions, and it’s where we are heading in the next chapter.

Chemical reactions

Most molecules are at peace with themselves. Bottles of sulfuric acid, sodium hydroxide, water, or acetone can be safely stored in a laboratory cupboard for years without any change in the chemical composition of the molecules inside. Yet if these compounds are mixed, chemical reactions, in some cases vigorous ones, will occur. This chapter is an introduction to the behaviour of organic molecules: why some react together and some don’t, and how to understand reactivity in terms of charges, orbitals, and the movement of electrons. We shall also be introducing a device for representing the detailed movement of electrons—the mechanism of the reaction—called the curly arrow.

To understand organic chemistry you need to be fluent in two languages. The first is the language of structure: of atoms, bonds, and orbitals. This language was the concern of the last three chapters: in Chapter 2 we looked at how to draw structures, in Chapter 3 how to find out what those structures are, and in Chapter 4 how to explain structure using electrons in orbitals.

But now we need to take up a second language: that of reactivity. Chemistry is first and foremost about the dynamic features of molecules—how to create new molecules from old ones, for example. To understand this we need new terminology and tools for explaining, predicting, and talking about reactions.

Molecules react because they move. Atoms have (limited) movement within molecules—you saw in Chapter 3 how the stretching and bending of bonds can be detected by infrared spectroscopy, and we explained in Chapter 4 how the σ bonds of alkanes (but not the π bonds of alkenes) rotate freely. On top of that, in a liquid or a gas whole molecules move around continuously. They bump into each other, into the walls of the container, maybe into solvent...
in a solution. It is all this incessant motion which drives reactions, and we first need to look at what happens when molecules collide.

**Not all collisions between molecules lead to chemical change**

Molecules are coated with a layer of electrons which occupy bonding and maybe non-bonding orbitals. As a result the surface of each molecule is negatively charged and by and large molecules repel each other. Reactions can occur only if a pair of molecules have enough energy to overcome this superficial repulsion. If they don’t, they will simply bounce off one another like two balls in pool or snooker, exchanging energy and moving off with new velocities, but remaining chemically unchanged. That minimum energy requirement for reaction—a barrier over which molecules must pass if they are to react—is known as the *activation energy*. In any sample of a compound, the molecules will have a range of energies, but at least some must have more than the activation energy if they are to react.

**Charge attraction brings molecules together**

If you mix a solution of sodium chloride with a solution of silver nitrate, electrostatic attraction between the Ag⁺ cations and Cl⁻ anions is enough to bring them together into a stable, crystalline ionic lattice of silver chloride, which precipitates from solution. Both ions are of course surrounded by electrons, but the deficit of negative charge in the Ag⁺ cation (one electron short of the full Ag complement of 47) is enough to overcome the repulsion between the rest of the electrons.

Direct reaction of a cation and an anion is rare with organic molecules because there are relatively few stable organic anions, and even fewer stable organic cations. A more common cause of organic reactions is attraction between a charged reagent (a cation or anion) and an organic compound that both possess a *dipole*. An example that we shall explore in this chapter (and which decorates the cover of this book) is the reaction between a carbonyl compound such as formaldehyde (methanal) and one of those few stable organic anions, cyanide (−CN, in the form of its salt NaCN). The carbonyl group of formaldehyde is polarized because oxygen is more electronegative than carbon (see p. 103). The negative cyanide ion is attracted to the positive end of the carbonyl group dipole.

Actually, it isn’t necessary for *either* reagent to be charged. Water also reacts with formaldehyde and this time it is the *lone pair* of electrons—the non-bonding pair of electrons located on the oxygen atom of the uncharged water molecule—that is attracted to the positive end of the carbonyl dipole.

**Orbital overlap brings molecules together**

Charges and dipoles can help bring molecules together for reaction, helping them to overcome their electronic repulsion and lowering their activation energy. But reactions can still take place even between completely uncharged molecules with no dipole, provided their molecular orbitals can interact. One of the old ‘tests’ for unsaturation was to treat a compound with bromine water. If the brown colour disappeared, the molecule was unsaturated (contained double bonds). Spectroscopy means we rarely need to use such tests now, but the reaction is still an important one. An alkene reacts with bromine, even though the alkene and the bromine molecule have neither charge nor dipole. The attraction between these molecules is not electrostatic; instead, their electronic repulsion is overcome because the bromine molecule has an empty orbital available—the σ* orbital of the Br–Br bond—which can accept electrons from the alkene. Unlike the repulsive interaction between filled orbitals, the interaction between a filled and an unfilled orbital can lead to attraction and reaction.

In fact, orbital interactions are also involved in the other two reactions on this page, but in those cases the orbital interactions are augmented by electrostatic attraction.
To summarize the situation:

- In general, molecules repel each other, and need to overcome a barrier with a minimum amount of activation energy in order to react.
- Most organic reactions involve interactions between full and empty orbitals.
- Many, but not all, also involve charge interactions, which help overcome electronic repulsion.
- Some ionic reactions involve nothing but charge attraction.

We don’t need to analyse whether charge or orbital interaction is the most important factor in bringing molecules together, but you do need to be aware that both may be involved to varying degrees.

Reactions happen when electrons flow between molecules

When, as a result of these interactions, a pair of molecules find themselves close together, a reaction can take place provided electrons move from one molecule to another. This is what we call the mechanism of the reaction—the detailed description of the pathway the electrons take. In most organic reactions, the electrons start in one molecule and move towards another. We call the molecule that accepts the electrons the electrophile (electron-lover) for obvious reasons. The molecule that donates the electrons is called the nucleophile.

A bond forms when electrons move from a nucleophile to an electrophile:

The nucleophile donates electrons.
The electrophile accepts electrons.

Here’s a very simple example where the nucleophile is an anion (Cl\(^{-}\)) and the electrophile is a cation (H\(^{+}\)). The two are brought together by charge attraction, and the new bond is formed by electrons donated by the nucleophile. Since we are representing the formation of a new bond by the movement of electrons, it’s natural to use an arrow to show the way the electrons flow. Arrows used to show electron flow are always curved: we call them ‘curly arrows’. The arrow showing the reaction itself is straight.

In the next example, neither the nucleophile (ammonia, NH\(_3\)) nor the electrophile (borane, BH\(_3\)) are charged, but they are drawn together by the interaction between the electrons of the non-bonding lone pair at N and the empty p orbital on B. Electrons flow from the nucleophile (NH\(_3\)) to the electrophile (BH\(_3\)) and a new bond is formed.

Bonding in BH\(_3\) and NH\(_3\) was discussed on p. 103.
The charges on the B and the N are necessary simply to account correctly for the electrons. Usually, we think of the pair of electrons in a bond as coming one from each of the bonded atoms. But here, since nitrogen donates both electrons (such bonds used to be called ‘dative bonds’) we have to account for the fact that boron ends up with one electron extra, and nitrogen one electron too few. The bond that forms is just a normal $\sigma$ bond.

**Orbital overlap is essential for successful reaction**

In the reaction of ammonia with borane, not only do the molecules have to collide with enough energy to react, but they must also collide with the orbitals aligned correctly for them to interact. As you saw in Chapter 3, the lone pair of the nitrogen atom resides in a filled, non-bonding sp$^3$ orbital. This orbital has to overlap with the empty p orbital on B to form a bond. So, a collision like this

```
H NH
H H
H B
```

will do just fine for making a bond, but collisions like these

```
H B
H
```

will not do at all.

Of course we can also draw a molecular orbital energy level diagram for the constructive, end-on interaction of the orbitals: look back to Chapter 4 to remind yourself of how to do this. Here, we need the filled sp$^3$ orbital on N to interact with the empty p orbital on B to give a new $\sigma$ bonding orbital and an empty $\sigma^*$ antibonding orbital. Finally, putting in the two electrons from the N's lone pair gives us a full picture of the new B–N bond.

The energy level diagram makes it clear why bonding is favourable too: the electrons have dropped down from the non-bonding sp$^3$ orbital to the new lower energy bonding $\sigma$ orbital. We don't need to consider what has happened to the energy of the unfilled orbitals because they're empty and don't contribute to the energy of the molecule as a whole.

We can generalize this idea to work out what makes a good nucleophile and a good electrophile. We’ll use an imaginary, generic nucleophile Nu, with a pair of electrons in some sort of filled orbital (it doesn't matter what this orbital is) which it can donate to the empty orbital of a generic electrophile E. Here are three versions of the molecular orbital energy level diagram:
On the left, the energies of the filled Nu orbital and the empty E orbital are almost the same. There is a significant gain in energy when the new bond forms between them. On the right, there is a large difference between the energies of the filled Nu orbital and the empty E orbital, and the energy gain is negligible. This tells us something: the best reactions are ones in which the energies of the interacting orbitals are similar in energy.

**For a reaction to take place, molecules must:**
- overcome their electronic repulsion by charge attraction and/or orbital overlap
- have orbitals of appropriate energy to interact—a filled orbital on the nucleophile and an empty orbital on the electrophile
- approach each other such that these orbitals can overlap to form a bonding interaction.

**Nucleophiles and electrophiles**

What does this mean for nucleophiles and electrophiles? Well, in general, filled orbitals tend to be low in energy—that is after all why they are filled! Conversely, empty orbitals tend to be high in energy. So the best interaction (the one that gains the new molecule the most energy) is likely to be between the highest in energy of all the filled orbitals—an orbital we can term the ‘highest occupied molecular orbital’ or HOMO for short—and the lowest in energy of all of the unfilled orbitals—the ‘lowest unoccupied molecular orbital’ or LUMO for short. This diagram may help clarify this idea—it’s a repeat of the best interaction above (the one on the left), but with other orbitals sketched in.
Remember, we can ignore all interactions between pairs of filled orbitals (bonding and antibonding cancel out, see p. 94) and pairs of unfilled orbitals (they don’t contain electrons so don’t contribute to the stability of the molecule). Of the interactions that are left, the one that gains the molecule the most energy is between the LUMO of the electrophile and the HOMO of the nucleophile. To make these orbitals as close as possible in energy, we want the nucleophile to have a high-energy HOMO and the electrophile to have a low-energy LUMO.

- The best nucleophiles have high-energy occupied molecular orbitals (HOMOs).
- The best electrophiles have low-energy unoccupied molecular orbitals (LUMOs).

The very first stage in understanding any reaction is to work out which of the reacting molecules is the nucleophile and which is the electrophile. It is impossible to stress too much how important it is to be able to identify nucleophiles and electrophiles correctly. For this reason we’ll now conduct an identity parade of each class. We’ll show you some of the top performing nucleophiles and top performing electrophiles, with a few comments on why they are so good at what they do, before we move on to see them in action.

### Identifying a nucleophile

Nucleophiles are either negatively charged or neutral species with a pair of electrons in a high-energy orbital (the HOMO). The most common type of nucleophile has a non-bonding lone pair of electrons. Non-bonding electrons are typically high in energy because they do not benefit from the stabilization bonding electrons get from being shared between two nuclei. Typical neutral nucleophiles with lone pairs are ammonia, amines, water, and alcohols, all of which have lone pairs (one for N, two of equal energy for O) occupying sp³ orbitals.

Other atoms later in the periodic table which carry lone pairs, such as phosphines, thiols, and sulfides, also make good nucleophiles, especially since their lone pairs are of even higher energy occupying orbitals made up of 3s and 3p atomic orbitals.

Anions which have lone pairs are often good nucleophiles too, partly because they can be attracted electrostatically by positively charged electrophiles. The anionic centre is usually O, S, or halogen, each of which can have several identical lone pairs. For example, hydroxide has three lone pairs—the negative charge cannot be assigned to one of them in particular. It’s convenient just to draw the negative charge, and not the lone pairs as well. Negative charges like this actually represent a pair of electrons—both the ‘extra’ electron and its partner in the lone pair—so we normally write mechanisms with an arrow starting on the negative charge.

The most important carbon nucleophile with a lone pair of electrons is the cyanide ion. Although linear cyanide (which is isoelectronic with N₂) has a lone pair on nitrogen and a lone pair on carbon, the nucleophilic atom is usually anionic carbon rather than neutral nitrogen as the sp orbital on carbon is of higher energy than that on the more electronegative nitrogen, and therefore constitutes the HOMO.
Molecules can still be nucleophilic without non-bonding lone pairs. The next highest set of orbitals are bonding $\pi$ orbitals, especially C=C double bonds, since they are higher in energy than $\sigma$ orbitals (see p. 93). Simple alkenes are weakly nucleophilic and react with strong electrophiles such as bromine. Note, however, that molecules with $\pi$ bonds can also be electrophiles, particularly when the $\pi$ bond involves an electronegative atom. The only common $\pi$ nucleophiles are alkenes and aromatic rings.

Finally, it is possible for the $\sigma$ bond of a nucleophile to donate electrons, provided it is a $\sigma$ bond associated with electropositive atoms such as B, Si, or the metals, along with C or H. You saw on p. 97 how the weak hold these atoms have over their electrons means that their atomic orbitals (and hence the molecular orbitals they contribute to) are high in energy. You met the borohydride anion BH$_4^-$ in Chapter 4. Borohydride is a good nucleophile—it attacks electrophilic carbonyl compounds, as you will see shortly. It donates electrons from its HOMO, the B–H $\sigma$ bond. Notice that in this case the negative charge does not represent a pair of electrons: you cannot start a curly arrow from it.

In later chapters you will see organometallics—compounds with carbon–metal bonds, for example methyllithium—acting as nucleophiles. They do so because the $\sigma$ orbital generated from electropositive C and even more electropositive Li is high in energy.

---

**Nucleophiles donate electrons from available, high-energy orbitals represented by one of the following:**

- $\text{NH}_3$
- Br
- $\text{H}_2\text{C}=$\text{CH}_2
- Li–CH$_3$

  a lone pair  a negative charge  a double bond  a $\sigma$ bond to an electropositive atom

The curly arrows in the box above represent electron movement away from the nucleophile. But the electrons have to go somewhere: they are donated to an electrophile.

**Identifying an electrophile**

Electrophiles are neutral or positively charged species with an empty atomic orbital (such as the empty $p$ orbital in borane) or a low-energy antibonding orbital that can easily accept electrons. The simplest electrophile is the hydrogen cation, $\text{H}^+$, usually named for what it is, a proton. $\text{H}^+$ is a species without any electrons at all and a vacant, very low energy, 1s orbital. It is so reactive that it is hardly ever found and almost any nucleophile will react with it. Acid solutions containing $\text{H}^+$ are neutralized by the nucleophile hydroxide, for example, and strong acid goes on to protonate water as well, the water acting as a nucleophile and the proton as the electrophile. The product is the hydronium ion, $\text{H}_3\text{O}^+$, the true acidic species in all aqueous strong acids. Here’s the reaction between hydroxide and $\text{H}^+$ with the electron movement from the nucleophile to the electrophile represented by curly arrows. The arrows start on the hydroxide’s negative charge, which represents one of the oxygen’s pairs of electrons:

Other electrophiles with empty atomic orbitals include borane, which you met on p. 103, and related compounds such as boron trifluoride and aluminium trichloride. BF$_3$ reacts with ethers, as shown below, to form stable complexes. This time the arrow starts on the lone pair.
Few organic compounds have vacant atomic orbitals and in most organic electrophiles the LUMOs are instead **low-energy antibonding orbitals associated with electronegative atoms**. These antibonding orbitals can be either \( \pi^* \) orbitals or \( \sigma^* \) orbitals—in other words, molecules which make good electrophiles might have a double or a single bond to an electronegative atom such as O, N, Cl, or Br. It’s important that an electronegative atom is involved in order to lower the energy of the orbital (see p. 96) and make it ready to accept electrons.

### Carbon’s place in the electronegativity scale

Here is a summary of electronegativities for atoms commonly involved in organic reactions.

This bar chart makes it clear why carbon is just so special: it can form strong bonds to almost anything, especially itself. Elements at either end of the scale form weak bonds to similar elements (metal–metal bonds are weak, as are halogen–halogen or O–O bonds), but elements in the middle can form strong bonds to other elements at either end of the scale or elements in the middle. Being in the middle also gives C versatile reactivity: it is electrophilic when bonded to a more electronegative element and nucleophilic when bonded to a more nucleophilic element.

The most important molecules with a **double bond to an electronegative atom** are carbonyl compounds. In fact carbonyl groups are the most important functional groups in organic chemistry. We looked at their orbitals on p. 103 and we devote the next chapter, Chapter 6, to a detailed study of their reactivity. The low-energy \( \pi^* \) orbital is available to accept electrons, and its electrophilicity is further enhanced by the partial positive charge at carbon which arises from the \( \text{C}=\text{O} \) dipole. Here’s an example of a carbonyl compound, acetone, reacting with an anionic nucleophile—we’ll choose borohydride in this case. Notice
how the arrow does not start on the negative charge, as the charge does not represent a pair of electrons here.

The arrows showing electron movement are a little more involved this time, but the explanation is straightforward. The first arrow shows the electrons moving from the nucleophile’s HOMO (the B–H \( \sigma \) orbital) to the electrophile’s LUMO (the C=O \( \pi^* \) orbital). The new feature in this mechanism is a second arrow showing the electrons moving from the double bond onto the oxygen atom. This is easy to explain. Since the reaction is putting electrons into an antibonding orbital (the \( \pi^* \)), a bond has to break. That breaking bond is the C=O \( \sigma \) bond (the \( \sigma \) bond remains intact). The electrons in the bond have to go somewhere and they end up as an extra lone pair (represented by the negative charge) on oxygen. The product has a new C–H \( \sigma \) bond in place of the C=O \( \pi \) bond.

Molecules with a single bond to electronegative atoms can also make good electrophiles. In compounds such as HCl or CH\(_3\)Br, the \( \sigma^* \) orbital is low in energy because of the electronegative Cl or Br (see p. 95) and the dipole attracts the electrons of the nucleophile to the H or C atom.

Here’s an example of hydrogen chloride acting as an electrophile with ammonia as the nucleophile. As with the carbonyl example above, we are putting electrons into an antibonding orbital, so a bond must break. This time the antibonding orbital is the H–Cl \( \sigma^* \), so the bond which breaks is the H–Cl \( \sigma \) bond.

You may recognize this reaction, and the one on p. 113, as the reaction between a base and an acid. All acid–base reactions are reactions between a nucleophile (the base) and an electrophile (the acid). We call an electrophile an acid if it is has an \( X–H \) bond (\( X \) being any atom) that loses H\(^+\) in its reactions. We call a nucleophile a base when it uses a lone pair to donate electrons to the \( X–H \) bond.

There is a little more to the definition of an acid, which we shall discuss in Chapter 8, where you will meet the term ‘Lewis acid’.

Some \( \sigma \) bonds are electrophilic even though they have no dipole at all. The bonds in the halogens I\(_2\), Br\(_2\), and Cl\(_2\) are a case in point. Bromine, for example, is strongly electrophilic because it has a weak Br–Br bond with a low energy \( \sigma^* \) orbital. Why is the \( \sigma^* \) low in energy? Well, bromine is slightly electronegative, but it is also large: it has to use 4s and 4p atomic orbitals for bonding, but these orbitals are large and diffuse, and overlap poorly, meaning the \( \sigma^* \) molecular orbital is not raised far in energy and can easily accept electrons. How different the situation is with a C–C bond: C–C single bonds are almost never electrophilic.
Bromine reacts with many nucleophiles, for example in the reaction shown below between a sulfide and bromine. Lone pair electrons are donated from sulfur into the Br–Br σ* orbital, which makes a new bond between S and Br, and breaks the old Br–Br bond.

The unreactivity of C–C bonds is why we think of structures in terms of a hydrocarbon skeleton and functional groups: the hydrocarbon framework is made up of strong C–C bonds with unreactive low-energy filled and high-energy empty orbitals, while the functional groups tend to involve electronegative and electropositive atoms, which react because they contribute to more accessible low-energy LUMOs or high-energy HOMOs.

**Curly arrows represent reaction mechanisms**

You have now seen several examples of curly arrows representing the movement of electrons during a reaction, and it is time to discuss them in detail. It is no exaggeration to say that this simple device is the one most powerful tool chemists have for explaining simply and accurately how reactions work—in other words the mechanisms of reactions. Curly arrows are to reactions what structural diagrams are to molecules. We discussed the guidelines for drawing structures in Chapter 2, explaining that although the structure of a molecule may be very complex, a good structural diagram will represent all of its important features without unnecessary detail. Curly arrows are similar: you have seen how reactions involve the overlap and summation of molecular orbitals to make new molecular orbitals, and the movement of electrons within those orbitals. Curly arrows allow us to represent all the important features of those interactions and electron movements very simply, without being concerned with unnecessary detail. It’s now time to outline some guidelines for writing mechanisms with curly arrows.

**Curly arrows show the movement of electrons**

A curly arrow represents the *movement of a pair of electrons* from a filled orbital into an empty orbital. You can think of the curly arrow as representing a pair of electrons thrown, like a
climber’s grappling hook, across from where he is standing to where he wants to go. In the simplest cases, the result of this movement is to form a bond between a nucleophile and an electrophile. Here are two examples we have already seen in which lone pair electrons are transferred to empty atomic orbitals.

A curly arrow always starts with its tail resting on the symbol representing a pair of electrons in a filled orbital—in this case the lone pair or the negative charge (which actually represents a lone pair). The head of the arrow indicates the final destination of the pair of electrons—the new bond between oxygen and hydrogen or oxygen and boron in these examples. As we are forming a new bond, the head of the arrow should be drawn to a point somewhere on the line between the two atoms.

Why does a curly arrow represent two electrons? Well, as you saw in Chapter 4, it takes two electrons to make a bond, and in these two cases those electrons come from a lone pair. We use a different sort of arrow for movements of one electron, as you will see in Chapters 24 and 37.

When the nucleophile attacks an antibonding orbital, such as the weak Br–Br bond we have just been discussing, we need two arrows, one to make the new bond and one to break the old.

The bond-making arrow is the same as before—it starts on the nucleophile’s lone pair and ends near the electrophile—but the bond-breaking arrow is new. This arrow shows that the two electrons in the bond move to one end (a bromine atom) and turn it into an anion. As always the arrow starts on something representing a pair of electrons in a filled orbital—the Br–Br σ bond. It should start in the centre of the bond and its head should rest on the atom (Br in this case) the electrons are heading for.

Another example is the attack of a base on the strong acid HBr.

It is not important how much curvature you put into the arrows—as long as they curl enough to distinguish them from straight reaction arrows, they can be as curly as you like. Neither does it matter whether they go to the left or the right, or whether they curve up or down as long as they begin and end in the right places. The mechanism below is just as correct:

---

Some chemists prefer to place this point halfway between the atoms but we think it is clearer and more informative if the arrowhead is closer to the atom to which the new bond is forming. For these examples the difference is minimal and either method is completely clear, but in more complex situations our method prevents ambiguity, as we shall see later. We shall adopt this convention throughout this book: that the arrow ends close to the electrophile.

Notice that the final arrow ends up delivering the electrons to an electronegative atom, satisfying its desire for electron density. This is part of the reason why double or single bonds to electronegative atoms are often a feature of good electrophiles.
Curly arrows always start on something representing a pair of electrons:
• a negative charge
• a lone pair
• or a bond

and end at the point those electrons are moving to.

**Charge is conserved in each step of a reaction**

Charge cannot be created or destroyed. If the starting materials have no overall charge, then neither must the products. In the last example above, it is obvious why the bromine becomes negatively charged—it takes both electrons from the bond even though only one of them formally ‘belongs’ to it. It may be less obvious to you why the ammonium cation has to have a positive charge, but it must, in order to maintain overall neutrality. One way to think about it is to note that both of the electrons in the new N–H bond come from N, so N is one electron down on the deal.

If the starting materials are charged, then the products must have, overall, the same charge. Here’s ammonia being protonated by H₃O⁺—both starting materials and products must have overall charge 1⁺.

When it is a π bond that is being broken rather than a σ bond, only the π bond is broken and the σ bond should be left in place. This is what commonly happens when an electrophilic carbonyl group is attacked by a nucleophile. Just as in the breaking of a σ bond, start the arrow in the middle of the π bond and end by putting the arrowhead on the more electronegative atom, in this case oxygen rather than carbon.

In this case the starting materials had an overall negative charge and this is preserved in the anionic product. The charge disappears from the hydroxide ion because it is now sharing a pair of electrons with what was the carbonyl carbon atom and a charge appears on what was the carbonyl oxygen atom because it now has one of the electrons in the old π bond.

**π bonds as nucleophiles**

As you saw above, alkenes can be nucleophiles. The reaction of an alkene with HBr is a simple example: the C–C π bond is the HOMO of the nucleophile. The first arrow therefore starts in the middle of the π bond and goes into the gap between one of the carbon atoms and the hydrogen atom of HBr. The second arrow takes the electrons out of the H–Br σ bond and puts them onto the bromine atom to make bromide ion. Overall charge is conserved, so we must generate a positively charged species called a carbocation. The carbocation has a positive charge and an empty π orbital (you can count the electrons to make sure).
Notice that it was important to draw the two reagents in the right orientation since we need the arrow to show which end of the alkene reacts with which end of HBr. If we had aligned them differently we would have had trouble drawing the mechanism. Here is a less satisfactory representation, in which the H doesn’t seem to transfer to the correct end of the alkene:

\[
\text{HB} \rightarrow \text{H} + \text{Br}^-
\]

If you find yourself making an ambiguous drawing like this, it is worth having another go to see if you can be clearer. When the nucleophile is a π (or σ) bond rather than a lone pair or a charge there is always the question of which end of the bond actually reacts. One way to make this clear is to draw an atom-specific curly arrow actually passing through the atom that reacts. Something like this will do:

This reaction does not, in fact, stop here as the two ions produced now react with each other to form the product of the reaction. The anion is the nucleophile and the carbocation, with its empty p orbital, is the electrophile.

\[
\text{Br} \rightarrow \text{Br}^{-}
\]

**σ bonds as nucleophiles**

When σ bonds act as nucleophiles, the electrons also have to go to one end of the σ bond as they form a new bond to the electrophile. We can return to an earlier example, the reaction of sodium borohydride (NaBH4) with a carbonyl compound, and complete the mechanism. In this example, one of the atoms (the hydrogen atom) moves away from the rest of the BH4 anion and becomes bonded to the carbonyl compound. The LUMO of the electrophile is, of course, the π* orbital of the C=O double bond.

\[
\text{H}_2\text{O}^{-} \rightarrow \text{H} + \text{O}^{-}
\]

The arrow from the nucleophile should start in the middle of the bond that breaks and show which atom is transferred to the electrophile. You could use an atom-specific arrow if you wanted to make it absolutely clear that the electrons in the σ bond act as a nucleophile through the hydrogen and not through the boron atom:

The anion which forms is an intermediate, not the final product. The reaction is often carried out in water and the anion acts as a nucleophile to remove a proton from water. Water is the electrophile: its LUMO is the O–H σ*.

\[
\text{H}_2\text{O}^{-} \rightarrow \text{HO}^{-} + \text{H}^+
\]
Summary: Curly arrow health check

- A curly arrow shows the movement of a pair of electrons.
- The tail of the arrow shows the source of the electron pair, which will be a filled orbital (HOMO) and can be represented by:
  - a lone pair
  - or a negative charge
  - or a π bond
  - or a σ bond.
- The head of the arrow indicates the destination of the electron pair, which will be:
  - an empty atomic orbital where a new bond will be formed
  - or a π* or σ* antibonding orbital where a new bond will be formed and an old bond will break
  - or an electronegative atom that can support a negative charge.
- Overall charge is always conserved in a reaction.

Drawing your own mechanisms with curly arrows

When you meet a new reaction, you must do two things:

1. identify which bonds have been formed and broken, and
2. decide which molecule is the nucleophile and which is the electrophile.

Once you have done that, you are well on the way to writing a reasonable mechanism using curly arrows. We’ll take as an example the reaction of triphenylphosphine with methyl iodide.

\[
\text{Mel} + \text{Ph}_3\text{P} \rightarrow \text{Ph}_3\text{P}=\text{Me} + \text{I}^\ominus
\]

First observe what has happened: a new bond has been formed between the phosphorus atom and the methyl group, and the carbon–iodine bond has been broken. So we need to draw the two reagents in such a way that a curly arrow can be used to represent this new bond. You’ll also need to make sure that you draw out all of the bonds that are actually involved in the reaction (too much detail is better than too little):

Now the all-important question: which is the nucleophile and which is the electrophile? For the nucleophile we are looking for a high-energy pair of electrons such as a lone pair, which the phosphorus has. Likewise, methyl iodide fits the bill as a plausible electrophile, with its bond between C and an electronegative element (I). All that remains is to draw the arrows. The first one starts on the source of the electrons, the phosphorus lone pair, and finishes near the C atom to indicate the new P–C bond. The second one breaks the old C–I bond and moves electrons onto the I atom.

Admittedly, that was quite an easy mechanism to draw but you should still be pleased if you succeeded at your first try.
Watch out for five-valent carbons

We now ought to spell out one thing that we have never stated but rather assumed. Most atoms in stable organic molecules have a full complement of electrons (two in the case of hydrogen, eight in the cases of carbon, nitrogen, and oxygen) and so, if you make a new bond to one of those elements, you must also break an existing bond. Suppose you just ‘added’ Ph₃P to MeI in this last example without breaking the C—I bond: what would happen?

This structure must be wrong because carbon cannot have five bonds—if it did it would have ten electrons in the 2s and the three 2p orbitals. Four orbitals can contain only eight electrons.

B, C, N, and O never have more than four bonds. If you make a new bond to uncharged H, C, N, or O you must also break one of the existing bonds in the same step.

Mechanisms with several steps

At the beginning of the chapter, we mentioned the fact that carbonyl compounds react with cyanide. We are now going to deduce a mechanism. This is the reaction:

We must decide what happens. NaCN is an ionic solid so the true reagent must be cyanide ion, whose structure was discussed on p. 112. As it is an anion, it must be the nucleophile and the carbonyl group must be the electrophile. Starting the arrow on the nucleophile’s negative charge and heading for the C=O group, and then using a second arrow to break the C=O bond gives us this:

This is a good mechanism but it doesn’t quite produce the product. There must be a second step in which the anionic oxygen picks up a proton from somewhere. The only source of protons is the solvent, water, so we can write the full mechanism in one sequence:

Try a more complicated example: primary alcohols can be converted into symmetrical ethers in acid solution. Suggest a mechanism for this acid-catalysed conversion of one functional group into another.
The acid must do something, so we need to start with the reaction between ethanol and H⁺. H⁺ has to be an electrophile, so the nucleophile must be ethanol, using its HOMO, one of the O lone pairs, as the source of electrons. The first intermediate we get is called an oxonium ion.

The positively charged oxonium ion has to be the electrophile in the second step of the reaction, and the only possible nucleophile is another molecule of ethanol. But how do they react? It's tempting to allow the ethanol's lone pair to attack the positively charged oxygen atom, but that would give us an oxygen atom with ten electrons—as with H₃O⁺ this positive charge is not an empty orbital. Attacking the H–O bond is a good alternative, but that just takes us back to where we started.

What we need is a new C–O bond, so the lone pair must attack at carbon, putting electrons into the C–O σ* and expelling a molecule of water. Here's the full mechanism. The last step is loss of the proton to give the ether.

Now for something completely new: try drawing a mechanism for this reaction.

You might well protest that you don't know anything about the chemistry of either of the functional groups, the thiol or the cyclic ether. Be that as it may, you can still draw a mechanism. Ask first of all: which bonds have been formed and which broken? Clearly the S–H bond has been broken and a new S–C bond formed. The three-membered ring has gone by the cleavage of one of the C–O bonds. The main chain of carbon atoms is unchanged. All this is sketched in the diagram in the margin. We suggest you now cover the rest of this page and try to work out a mechanism yourself before reading further.

The hydroxide must do something, and since it is negatively charged, a reasonable starting point is going to be to use it as a nucleophile to break the S–H bond. Hydroxide is after all a base; it likes to remove protons. So here's the first step:

Now we have a negatively charged sulfur atom, which must be the nucleophile. We want to make a bond to carbon, so the C–O bond in the three-membered ring must be the electrophile. So ... just draw the arrows and see what happens. Here goes ...
That is not quite the product: we need to let this anion pick up a proton from somewhere. Where can the proton come from? It must be the proton originally removed by the hydroxide. The anion attacks water and the hydroxide is regenerated.

Your mechanism possibly didn’t look as neat as the printed version, but if you got it roughly right, you should be proud. This is a three-step mechanism involving chemistry that is new to you and yet you could draw a mechanism for it.

**Curly arrows are vital for learning organic chemistry**

Curly arrows can be used to explain the interaction between the structure of reactants and products, and their reactivity in the vast majority of organic reactions, regardless of their complexity. When used correctly they can even be used to predict possible outcomes of unknown processes and hence to design new synthetic reactions. They are a powerful tool for understanding and developing organic chemistry and it is vital that you become proficient in their use. They are the dynamic language of organic reaction mechanisms and they will appear in every chapter of the book from now on.

Another equally important reason for mastering curly arrows now, as we start the systematic study of different types of reactions, is that the seemingly vast number of ‘different reactions’ turn out not to be so vast after all. Most organic reactions involve the movement of pairs of electrons between nucleophiles and electrophiles. And with relatively few types of organic nucleophiles and electrophiles involved in all these reactions, the similarity between seemingly unrelated reactions will become immediately apparent if you understand and can draw mechanisms. Learning to draw mechanisms means you can understand groups of related reactions rather than having to learn them individually.

Drawing curly arrow mechanisms is a bit like riding a bike. Before you’ve mastered the skill, you keep falling off. Once you’ve mastered the skill, it seems so straightforward that you wonder how you ever did without it. You’ll come across busy streets and complex traffic junctions, but with care you’ll get through safely.

**Step-by-step guide to drawing mechanisms with curly arrows**

If you still feel you are at the wobbly stage, and need a helping hand, this step-by-step guide may help you. You’ll soon find you won’t need to follow it through in detail.

1. Draw out the reagents as clear structures following the guidelines in Chapter 2. Check that you understand what the reagents and the solvent are under the conditions of the reaction, for example if the reaction is in a base, will one of the compounds exist as an anion?
2. Inspect the starting materials and the products, and assess what has happened in the reaction. What new bonds have been formed? What bonds have been broken? Has anything been added or removed? Have any bonds moved around the molecule?
3. Identify the nucleophilic centres in all the reactant molecules and decide which is the most nucleophilic. Then identify the electrophiles present and again decide which is the most electrophilic.
4. If the combination of these two centres appears to lead to the product, draw the reactants, complete with charges, so as to position the nucleophilic and electrophilic centres within bonding distance, ensuring that the angle of attack of the nucleophile is more or less consistent with the orbitals involved.
5. Draw a curly arrow from the nucleophile to the electrophile. It must start on a representation of electrons—a filled orbital or negative charge (show this clearly by just touching the bond or charge)—and finish where the electrons are heading for (show this clearly by the position of the head).

---

**We will generally show mechanisms using black arrows on red diagrams but the only point of that is to make the arrows stand out. We suggest that when you write mechanisms you consider using a colour for your arrows that contrasts with the structures.**

---

**The few reaction types that don’t involve nucleophiles and electrophiles are discussed in Chapters 34, 35, 37, and 38.**

**You will see a great example of this in Chapter 10: carboxylic acids, amides, esters, anhydrides … many functional groups, but all the same mechanisms.**
6. Consider whether any atom that has been changed now has too many bonds; if so one of them must be broken to avoid absurd structures. Select a bond to break. Draw a curly arrow from the centre of the chosen bond, the filled orbital, and terminate it in a suitable place, such as an electronegative atom.

7. Write out the structures of the products specified by the curly arrows. Break the bonds that are the sources of the arrows and make those that are the targets. Consider the effect on the charges on individual atoms and check that the overall charge is not changed. Once you have drawn the curly arrows, the structure of the products is already decided and there is no room for any further decisions. Just write what the curly arrows tell you. If the structure is wrong, then the curly arrows were wrong so go back and change them.

8. Repeat stages 5–7 as required to produce a stable product.

Now you have met the language of mechanism it’s time to look in detail at the reactions of some functional groups, and we start with the most important functional group of all, the carbonyl group.

Further reading

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Nucleophilic addition to the carbonyl group

Molecular orbitals explain the reactivity of the carbonyl group

We are now going to leave to one side most of the reactions you met in the last chapter—we will come back to them all again later in the book. In this chapter we are going to concentrate on just one of them—probably the simplest of all organic reactions—the addition of a nucleophile to a carbonyl group. The carbonyl group, as found in aldehydes, ketones, and many other compounds, is without doubt the most important functional group in organic chemistry, and that is another reason why we have chosen it as our first topic for more detailed study.

You met nucleophilic addition to a carbonyl group on pp. 115 and 121, where we showed you how cyanide reacts with aldehydes to give an alcohol. As a reminder, here is the reaction again, this time with a ketone, with its mechanism.

\[
\begin{align*}
\text{NaCN, H}_2\text{SO}_4 & \\
\text{H}_2\text{O} & \\
\end{align*}
\]

The reaction has two steps: nucleophilic addition of cyanide, followed by protonation of the anion. In fact, this is a general feature of all nucleophilic additions to carbonyl groups.
Additions to carbonyl groups generally consist of two mechanistic steps:
- nucleophilic attack on the carbonyl group
- protonation of the anion that results.

The addition step is more important, and it forms a new C–C σ bond at the expense of the C=O π bond. The protonation step makes the overall reaction addition of HCN across the C=O π bond.

Why does cyanide, in common with many other nucleophiles, attack the carbonyl group? And why does it attack the carbon atom of the carbonyl group? To answer these questions we need to look in detail at the structure of carbonyl compounds in general and the orbitals of the C=O group in particular.

The carbonyl double bond, like that found in alkenes (whose bonding we discussed in Chapter 4), consists of two parts: one σ bond and one π bond. The σ bond between the two sp² hybridized atoms—carbon and oxygen—is formed from two sp² orbitals. The other sp² orbitals on carbon form the two σ bonds to the substituents while those on oxygen are filled by the two lone pairs. The sp² hybridization means that the carbonyl group has to be planar, and the angle between the substituents is close to 120°. The diagram illustrates all this for the simplest carbonyl compound, formaldehyde (or methanal, CH₂O). The π bond then results from overlap of the remaining p orbitals—again, you can see this for formaldehyde in the diagram.

When we introduced the bonding in the carbonyl group in Chapter 4 we explained how polarization in the π bond means it is skewed towards oxygen, because oxygen is more electronegative than carbon. Conversely, the unfilled π* antibonding orbital is skewed in the opposite direction, with a larger coefficient at the carbon atom. This is quite hard to represent with the π bond represented as a single unit, as shown above, but becomes easier to visualize if instead we represent the π and π* orbitals using individual p orbitals on C and O. The diagrams in the margin show the π and π* orbitals represented in this way.

<table>

</tr>
<tr>
<td>C=O</td>
</tr>
</tbody>
</table>

Because there are two types of bonding between C and O, the C=O double bond is rather shorter than a typical C–O single bond, and also over twice as strong—so why is it so reactive? Polarization is the key. The polarized C=O bond gives the carbon atom some degree of positive charge, and this charge attracts negatively charged nucleophiles (like cyanide) and encourages reaction. The polarization of the antibonding π* orbital towards carbon is also
important because, when the carbonyl group reacts with a nucleophile, electrons move from the HOMO of the nucleophile (an sp orbital in the case of cyanide) into the LUMO of the electrophile—in other words the $\pi^*$ orbital of the $\text{C}=\text{O}$ bond. The greater coefficient of the $\pi^*$ orbital at carbon means a better HOMO–LUMO interaction, so this is where the nucleophile attacks.

As our nucleophile—which we are representing here as ‘Nu$^-$’—approaches the carbon atom, the electron pair in its HOMO starts to interact with the LUMO (antibonding $\pi^*$) to form a new $\sigma$ bond. Filling antibonding orbitals breaks bonds and, as the electrons enter the antibonding $\pi^*$ of the carbonyl group, the $\pi$ bond is broken, leaving only the $\text{C}–\text{O} \ \sigma$ bond intact. But electrons can’t just vanish, and those that were in the $\pi$ bond move off on to the electronegative oxygen, which ends up with the negative charge that started on the nucleophile. You can see all this happening in the diagram below.

Notice how the trigonal, planar sp$^2$ hybridized carbon atom of the carbonyl group changes to a tetrahedral, sp$^3$ hybridized state in the product. For each class of nucleophile you meet in this chapter, we will show you the HOMO–LUMO interaction involved in the addition reaction. These interactions also show you how the orbitals of the starting materials change into the orbitals of the product as they combine. Most importantly here, the lone pair of the nucleophile combines with the $\pi^*$ of the carbonyl group to form a new $\sigma$ bond in the product.

**Attack of cyanide on aldehydes and ketones**

Now that we’ve looked at the theory of how a nucleophile attacks a carbonyl group, let’s go back to the real reaction with which we started this chapter: cyanohydrin formation from a carbonyl compound and sodium cyanide. Cyanide contains sp hybridized C and N atoms, and its HOMO is an sp orbital on carbon. The reaction is a typical nucleophilic addition reaction to a carbonyl group: the electron pair from the HOMO of the CN$^-$ (an sp orbital on carbon) moves into the C=O $\pi^*$ orbital; the electrons from the C=O $\pi$ orbital move on to the oxygen atom. The reaction is usually carried out in the presence of acid, which protonates the resulting alkoxide to give the hydroxyl group of the composite functional group known as a cyanohydrin. The reaction works with both ketones and aldehydes, and the mechanism below shows the reaction of a general aldehyde. This reaction appeared first in Chapter 5.
Cyanohydrins are important synthetic intermediates, for example the cyanohydrin formed from this cyclic amino ketone is the first intermediate in a synthesis of some medicinal compounds known as 5HT$_3$ agonists, which were designed to reduce nausea in chemotherapy patients.

Cyanohydrins are also components of many natural and industrial products, such as the insecticide cypermethrin (marketed as ‘Ripcord’ and ‘Barricade’).

Cyanohydrin formation is reversible: just dissolving a cyanohydrin in water can give back the aldehyde or ketone you started with, and aqueous base usually decomposes cyanohydrins completely. This is because cyanide is a good leaving group—we’ll come back to this type of reaction in more detail in Chapter 10.

Cyanohydrin formation is therefore an equilibrium between starting materials and products, and we can get good yields only if the equilibrium favours the products. The equilibrium is more favourable for aldehyde cyanohydrins than for ketone cyanohydrins, and the reason is the size of the groups attached to the carbonyl carbon atom. As the carbonyl carbon atom changes from sp$^2$ to sp$^3$, its bond angles change from about 120° to 109°.
about 109°—in other words, the substituents it carries move closer together. This reduction in bond angle is not a problem for aldehydes, because one of the substituents is just a (very small) hydrogen atom, but for ketones, especially ones that carry larger alkyl groups, this effect can disfavour the addition reaction. Effects that result from the size of substituents and the repulsion between them are called steric effects, and we call the repulsive force experienced by large substituents steric hindrance. Steric hindrance (not ‘hinderance’) is a consequence of repulsion between the electrons in all the filled orbitals of the alkyl substituents.

**Steric hindrance**

The size of substituents plays a role in very many organic reactions—it’s the reason aldehydes (with an H next to the C=O group) are more reactive than ketones, for example. Steric hindrance affects reaction rates, but also makes molecules react by completely different mechanisms, as you will see in the substitution reactions in Chapter 15. You will need to get used to thinking about whether the presence of large substituents, with all their filled C–H and C–C bonds, is a factor in determining how well a reaction will go.

**Cyanohydrins and cassava**

The reversibility of cyanohydrin formation is of more than theoretical interest. In parts of Africa the staple food is cassava. This food contains substantial quantities of the glucoside of acetone cyanohydrin (a glucoside is an acetal derived from glucose). We shall discuss the structure of glucose later in this chapter, but for now, just accept that it stabilizes the cyanohydrin.

The glucoside is not poisonous in itself, but enzymes in the human gut break it down and release HCN. Eventually 50 mg HCN per 100 g of cassava can be released and this is enough to kill a human being after a meal of unfermented cassava. If the cassava is crushed with water and allowed to stand (‘ferment’), enzymes in the cassava will do the same job and then the HCN can be washed out before the cassava is cooked and eaten.

The cassava is now safe to eat but it still contains some glucoside. Some diseases found in eastern Nigeria can be traced to long-term consumption of HCN. Similar glucosides are found in apple pips and the kernels inside the stones of fruit such as peaches and apricots. Some people like eating these, but it is unwise to eat too many at one sitting!

**The angle of nucleophilic attack on aldehydes and ketones**

Having introduced you to the sequence of events that makes up a nucleophilic attack at C=O (interaction of HOMO with LUMO, formation of new σ bond, breakage of π bond), we should now tell you a little more about the direction from which the nucleophile approaches the carbonyl group. Not only do nucleophiles always attack carbonyl groups at carbon, but they also always approach from a particular angle. You may at first be surprised by this angle, since nucleophiles attack not from a direction perpendicular to the plane of the carbonyl group but at about 107° to the C=O bond—close to the angle at which the new bond will form. This approach route is known as the Bürgi–Dunitz trajectory after the authors of the elegant crystallographic methods that revealed it. You can think of the angle of attack as the result of a compromise between maximum orbital overlap of the HOMO with π* and minimum repulsion of the HOMO by the electron density in the carbonyl π bond. But a better explanation is that π* does not have parallel atomic orbitals as there is a node halfway down the bond (Chapter 4) so the atomic orbitals are already at an angle. The nucleophile attacks along the axis of the larger orbital in the HOMO.
Although we now know precisely from which direction the nucleophile attacks the C=O group, this is not always easy to represent when we draw curly arrows. As long as you bear the Bürgi–Dunitz trajectory in mind, you are quite at liberty to write any of the variants shown here, among others.

Any other portions of the molecule that get in the way of (or, in other words, that cause *steric hindrance* to) the Bürgi–Dunitz trajectory will greatly reduce the rate of addition and this is another reason why aldehydes are more reactive than ketones. The importance of the Bürgi–Dunitz trajectory will become more evident later, particularly in Chapter 33.

Bürgi and Dunitz deduced this trajectory by examining crystal structures of compounds containing both a nucleophilic nitrogen atom and an electrophilic carbonyl group. They found that, when the two got close enough to interact, but were not free to undergo reaction, the nitrogen atom always lay on or near the 107° trajectory described here. Theoretical calculations later gave the same 107° value for the optimum angle of attack.

**Nucleophilic attack by ‘hydride’ on aldehydes and ketones**

Nucleophilic attack by the hydride ion, H\(^-\), is an almost unknown reaction. This species, which is present in the salt sodium hydride, NaH, has such a high charge density that it only ever reacts as a base. The reason is that its filled 1s orbital is of an ideal size to interact with the hydrogen atom's contribution to the \(\sigma^*\) orbital of an H–X bond (X can be any atom), but much too small to interact easily with carbon’s more diffuse 2p orbital contribution to the LUMO \((\pi^*)\) of the C=O group.

Nevertheless, adding H\(^-\) to the carbon atom of a C=O group would be a very useful reaction, as the result would be the formation of an alcohol. This process would involve going down from the aldehyde or ketone oxidation level to the alcohol oxidation level (Chapter 2, p. 32) and would therefore be a reduction. It cannot be done with NaH, but it can be done with some other compounds containing nucleophilic hydrogen atoms.

The most important of these compounds is sodium borohydride, NaBH\(_4\). This is a water-soluble salt containing the tetrahedral BH\(_4^-\) anion, which is isoelectronic with methane but has a negative charge since boron has one less proton in the nucleus than does carbon.
In Chapter 4 we looked at isoelectronic borane BH$_3$ and the cation CH$_3^+$. Here we have effectively added a hydride ion to each of them.

But beware! Remember (p. 115) there is no lone pair on boron: you must not draw an arrow coming out of this negative charge to form another bond. If you did, you would get a pentacovalent B(V) compound, which would have ten electrons in its outer shell. Such a thing is impossible with a first-row element as there are only four available orbitals ($1 \times 2s$ and $3 \times 2p$).

Instead, since all of the electrons (including those represented by the negative charge) are in B–H $\sigma$ bonds, it is from a B–H bond that we must start any arrow to indicate reaction of BH$_4^-$ as a nucleophile. By transferring this pair of electrons we make the boron atom neutral—it is now trivalent with just six electrons.

What happens when we carry out this reaction using a carbonyl compound as the electrophile? The hydrogen atom, together with the pair of electrons from the B–H bond, will be transferred to the carbon atom of the C=O group. Although no hydride ion, H$,^-$, is actually involved in the reaction, the transfer of a hydrogen atom with an attached pair of electrons can be regarded as a ‘hydride transfer’. You will often see it described this way in books. But be careful not to confuse BH$_4^-$ with the hydride ion itself. To make it quite clear that it is the hydrogen atom that is forming the new bond to C, this reaction may also be helpfully represented with a curly arrow passing through the hydrogen atom.

You met this reaction in Chapter 5 but there is more to say about it. The oxyanion produced in the first step can help stabilize the electron-deficient BH$_3$ molecule by adding to its empty p orbital. Now we have a tetravalent boron anion again, which could transfer a second hydrogen atom (with its pair of electrons) to another molecule of aldehyde.

This process can continue so that, in principle, all four hydrogen atoms could be transferred to molecules of aldehyde. In practice the reaction is rarely as efficient as that, but aldehydes and ketones are usually reduced in good yield to the corresponding alcohol by sodium borohydride in water or alcoholic solution. The water or alcohol solvent provides the proton needed to form the alcohol from the alkoxide.
Sodium borohydride is one of the weaker hydride donors. The fact that it can be used in water is evidence of this: more powerful hydride donors such as lithium aluminium hydride, LiAlH₄, react violently with water. Sodium borohydride reacts with both aldehydes and ketones, although the reaction with ketones is slower: for example, benzaldehyde is reduced about 400 times faster than acetophenone in isopropanol. This is because of steric hindrance (see above). Sodium borohydride does not react at all with less reactive carbonyl compounds such as esters or amides: if a molecule contains both an aldehyde and an ester, only the aldehyde will be reduced.

The next two examples illustrate the reduction of aldehydes and ketones in the presence of other reactive functional groups. No reaction occurs at the nitro group in the first case or at the alkyl halide in the second.

**Addition of organometallic reagents to aldehydes and ketones**

Organometallic compounds have a carbon–metal bond. Lithium and magnesium are very electropositive metals, and the Li–C or Mg–C bonds in organolithium or organomagnesium reagents are highly polarized towards carbon. They are therefore very powerful nucleophiles, and attack the carbonyl group to give alcohols, forming a new C–C bond. For our first example, we shall take one of the simplest of organolithiums, methyllithium, which is commercially available as a solution in Et₂O, shown here reacting with an aldehyde. The orbital diagram of the addition step shows how the polarization of the C–Li bond means that it is the carbon atom of the nucleophile that attacks the carbon atom of the electrophile and we get a new C–C bond.

We explained on p. 113 the polarization of bonds between carbon and more electropositive elements. The relevant electronegativities are C 2.5, Li 1.0, and Mg 1.2 so both metals are much more electropositive than carbon. The orbitals of MeLi are discussed in Chapter 4.

The course of the reaction is much the same as you have seen before, but we need to highlight a few points where this reaction scheme differs from those you have met earlier in the chapter. First of all, notice the legend ‘1. MeLi, THF; 2. H₂O’. This means that, first, MeLi is added to the aldehyde in a THF solvent. Reaction occurs: MeLi adds to the aldehyde to give an alkoxide. Then (and only then) water is added to protonate the alkoxide. The ‘2. H₂O’ means that water is added in a separate step only when all the MeLi has reacted: it is not present at the start of the reaction as it was in the cyanide reaction and some of the borohydride addition reactions. In fact, water must not be present during the addition of MeLi (or of any other organometallic reagent) to a carbonyl group because water destroys organometallics very rapidly.
by protonating them to give alkanes (organolithiums and organomagnesiums are strong bases as well as powerful nucleophiles). The addition of water, or sometimes dilute acid or ammonium chloride, at the end of the reaction is known as the work-up.

Because they are so reactive, organolithiums are usually used at low temperature, often –78 °C (the sublimation temperature of solid CO₂), in aprotic solvents such as Et₂O or THF. Protic solvents such as water or alcohols have acidic protons but aprotic solvents such as ether do not. Organolithiums also react with oxygen, so they have to be handled under a dry, inert atmosphere of nitrogen or argon. Other common, and commercially available, organolithium reagents include n-butyllithium and phenyllithium, and they react with both aldehydes and ketones. Note that addition to an aldehyde gives a secondary alcohol while addition to a ketone gives a tertiary alcohol.

Addition of water to aldehydes and ketones

Nucleophiles don’t have to be highly polarized or negatively charged to react with aldehydes and ketones: neutral ones will as well. How do we know? This $^{13}$C NMR spectrum was obtained by dissolving formaldehyde, H₂C=O, in water. You will remember from Chapter 3 that the carbon atoms of carbonyl groups give $^{13}$C signals typically in the region of 150–200 ppm. So where is formaldehyde’s carbonyl peak? Instead we have a signal at 83 ppm—where we would expect tetrahedral carbon atoms singly bonded to oxygen to appear.
What has happened is that water has added to the carbonyl group to give a compound known as a hydrate or 1,1-diol.

\[
\text{H}_2\text{O} + \text{RCHO} \rightarrow \text{RCHO} \cdot \text{H}_2\text{O} \quad \text{hydrate or 1,1-diol}
\]

This reaction, like the addition of cyanide we discussed at the beginning of the chapter, is an equilibrium, and is quite general for aldehydes and ketones. But, as with the cyanohydrins, the position of the equilibrium depends on the structure of the carbonyl compound. Generally, the same steric factors (p. 129) mean that simple aldehydes are hydrated to some extent while simple ketones are not. However, special factors can shift the equilibrium towards the hydrated form even for ketones, particularly if the carbonyl compound is reactive or unstable.

Formaldehyde is an extremely reactive aldehyde as it has no substituents to hinder attack—it is so reactive that it is rather prone to polymerization. And it is quite happy to move from sp\(^2\) to sp\(^3\) hybridization because there is very little increased steric hindrance between the two hydrogen atoms as the bond angle changes from 120° to 109° (p. 129). This is why our aqueous solution of formaldehyde contains essentially no CH\(_2\)O—it is completely hydrated. A mechanism for the hydration reaction is shown below. Notice how a proton has to be transferred from one oxygen atom to the other, mediated by water molecules.

Formaldehyde reacts with water so readily because its substituents are very small: a steric effect. Electronic effects can also favour reaction with nucleophiles—electron-negative atoms such as halogens attached to the carbon atoms next to the carbonyl group can increase the extent of hydration by the inductive effect according to the number of halogen substituents and their electron-withdrawing power. They increase the polarization of the carbonyl group, which already has a positively polarized carbon atom, and make it even more prone to attack by water. Trichloroacetaldehyde (chloral, Cl\(_3\)CHO) is hydrated completely in water, and the product ‘chloral hydrate’ can be isolated as crystals and is an anaesthetic.

You can see this quite clearly in the two IR spectra below. The first one is a spectrum of chloral hydrate from a bottle—notice there is no strong absorption between 1700 and 1800 cm\(^{-1}\) (where we would expect C=O to appear) and instead we have the tell-tale broad O–H peak at 3400 cm\(^{-1}\). Heating drives off the water, and the second IR spectrum is of the resulting dry chloral: the C=O peak has reappeared at 1770 cm\(^{-1}\) and the O–H peak has gone.

---

**Steric and electronic effects**

- **Steric effects** are concerned with the size and shape of groups within molecules.
- **Electronic effects** result from the way that electronegativity differences between atoms affect the way electrons are distributed in molecules. They can be divided into inductive effects, which are the consequence of the way that electronegativity differences lead to polarization of \(\sigma\) bonds, and conjugation (sometimes called mesomeric effects) which affects the distribution of electrons in \(\pi\) bonds and is discussed in the next chapter.

Steric and electronic effects are two of the main factors dominating the reactivity of nucleophiles and electrophiles.
The chart shows the extent of hydration (in water) of a small selection of carbonyl compounds: hexafluoroacetone is probably the most hydrated carbonyl compound possible! The larger the equilibrium constant, the more the equilibrium is to the right.

Cyclopropanones—three-membered ring ketones—are also hydrated to a significant extent, but for a different reason. You saw earlier how acyclic ketones suffer increased steric hindrance when the bond angle changes from 120° to 109° on moving from sp² to sp³ hybridization. Cyclopropanones (and other small-ring ketones) conversely prefer the small bond angle because their substituents are already confined within a ring. Look at it this way: a three-membered ring is really very strained, with bond angles forced to be 60°. For the sp² hybridized ketone this means bending the bonds 60° away from their ‘natural’ 120°. But for the sp³ hybridized hydrate the bonds have to be distorted by only 49° (= 109° – 60°). So addition to the C=O group allows some of the strain inherent in the small ring to be released—hydration is favoured, and indeed cyclopropanone and cyclobutanone are very reactive electrophiles.

The same structural features that favour or disfavour hydrate formation are important in determining the reactivity of carbonyl compounds with other nucleophiles, whether the reactions are reversible or not. Steric hindrance and more alkyl substituents make carbonyl compounds less reactive towards any nucleophile; electron-withdrawing groups and small rings make them more reactive.

**Hemiacetics from reaction of alcohols with aldehydes and ketones**

Since water adds to (at least some) carbonyl compounds, it should come as no surprise that alcohols do too. The product of the reaction is known as a hemiacetal, because it is halfway to
an acetal, a functional group that you met in Chapter 2 (p. 32) and that will be discussed in detail in Chapter 11. The mechanism follows in the footsteps of hydrate formation: just use ROH instead of HOH.

In the mechanism above, as in the mechanism of hydrate formation on p. 134, a proton has to be transferred between one oxygen atom and the other. We have shown a molecule of ethanol (or water) doing this, but it is impossible to define exactly the path taken by any one proton as it transfers between the oxygen atoms. It might not even be the same proton: another possible mechanism is shown below on the left, where a molecule of ethanol simultaneously gives away one proton and takes another. In the simplest case, the proton just hops from one oxygen to another, as shown in the right, and there is no shame in writing this mechanism: it is no more or less correct than the others.

What is certain is that proton transfers between oxygen atoms are very fast and are reversible, and for that reason we don’t need to be concerned with the details—the proton can always get to where it needs to be for the next step of the mechanism. As with all these carbonyl group reactions, what is really important is the addition step, not what happens to the protons.

Hemiacetal formation is reversible, and hemiacetals are stabilized by the same special structural features as those of hydrates. However, hemiacetals can also gain stability by being cyclic—when the carbonyl group and the attacking hydroxyl group are part of the same molecule. The reaction is now an intramolecular (within the same molecule) addition, as opposed to the intermolecular (between two molecules) ones we have considered so far.

Although the cyclic hemiacetal (also called lactol) product is more stable, it is still in equilibrium with some of the open-chain hydroxyaldehyde form. Its stability, and how easily it
forms, depends on the size of the ring: five- and six-membered rings are free from strain (their bonds are free to adopt 109° or 120° angles—compare the three-membered rings on p. 135), and five- or six-membered hemiacetals are common. Among the most important examples are many sugars. Glucose, for example, is a hydroxylaldehyde that exists mainly as a six-membered cyclic hemiacetal (>99% of glucose is cyclic in solution), while ribose exists as a five-membered cyclic hemiacetal.

Ketones also form hemiacetals

Hydroxyketones can also form hemiacetals but, as you should expect, they usually do so less readily than hydroxylaldehydes. But we know that this hydroxyketone must exist as the cyclic hemiacetal as it has no C=O stretch in its IR spectrum. The reason? The hydroxyketone is already cyclic, with the OH group poised to attack the ketone—it can’t get away so cyclization is highly favoured.

Acid and base catalysis of hemiacetal and hydrate formation

In Chapter 8 we shall look in detail at acids and bases, but at this point we need to tell you about one of their important roles in chemistry: they act as catalysts for a number of carbonyl addition reactions, among them hemiacetal and hydrate formation. To see why, we need to look back at the mechanisms of hemiacetal formation on p. 138 and hydrate formation on p. 134. Both involve proton-transfer steps, which we can choose to draw like this:

In the first proton-transfer step, ethanol acts as a base, removing a proton; in the second it acts as an acid, donating a proton. You saw in Chapter 5 how water can also act as an acid or a base. Strong acids or strong bases (for example HCl or NaOH) increase the rate of hemiacetal or hydrate formation because they allow these proton-transfer steps to occur before the addition to the carbonyl group.

In acid (dilute HCl, say), the mechanism is different in detail. The first step is now protonation of the carbonyl group’s lone pair: the positive charge makes it much more electrophilic.
so the addition reaction is faster. Notice how the proton added at the beginning is lost again at the end—it is really a catalyst.

The mechanism in basic solution is slightly different again. The first step is now deprotonation of the ethanol by hydroxide, which makes the addition reaction faster by making the ethanol more nucleophilic. Again, base (hydroxide) is regenerated in the last step, making the overall reaction catalytic in base.

The final step could equally well involve deprotonation of ethanol to give alkoxide—and alkoxide could equally well do the job of catalysing the reaction. In fact, you will often come across mechanisms with the base represented just as ‘B−’ because it doesn’t matter what the base is.

**For nucleophilic additions to carbonyl groups:**
- acid catalysts work by making the carbonyl group more electrophilic
- base catalysts work by making the nucleophile more nucleophilic
- both types of catalysts are regenerated at the end of the reaction.

**Bisulfite addition compounds**

The last nucleophile of this chapter, sodium bisulfite (NaHSO₃) adds to aldehydes and some ketones to give what is usually known as a **bisulfite addition compound**. The reaction occurs by nucleophilic attack of a lone pair on the carbonyl group, just like the attack of cyanide. This leaves a positively charged sulfur atom but a simple proton transfer leads to the product.

The products are useful for two reasons. They are usually crystalline and so can be used to purify liquid aldehydes by recrystallization. This is of value only because this reaction, like
several you have met in this chapter, is reversible. The bisulfite compounds are made by mixing the aldehyde or ketone with saturated aqueous sodium bisulfite in an ice bath, shaking, and crystallizing. After purification the bisulfite addition compound can be hydrolysed back to the aldehyde in dilute aqueous acid or base.

\[
\begin{align*}
\ce{R\!H} + \ce{NaHSO3} & \xrightarrow{\text{stir together in ice bath}} \ce{R\!SO3Na}^+ \ce{H}\cdot\ce{SO3^-Na}^- \\
& \xrightarrow{\text{dilute acid or base}} \text{crystalline solid}
\end{align*}
\]

The reversibility of the reaction makes bisulfite compounds useful intermediates in the synthesis of other adducts from aldehydes and ketones. For example, one practical method for making cyanohydrins involves bisulfite compounds. The famous practical book 'Vogel' suggests reacting acetone first with sodium bisulfite and then with sodium cyanide to give a good yield (70%) of the cyanohydrin.

What is happening here? The bisulfite compound forms first, but only as an intermediate on the route to the cyanohydrin. When the cyanide is added, reversing the formation of the bisulfite compound provides the single proton necessary to give back the hydroxyl group at the end of the reaction. No dangerous HCN is released (always a hazard when cyanide ions and acid are present together).

\[
\begin{align*}
\ce{Me\!Me\!Me\!Me} & \xrightarrow{1. \ce{NaHSO3}} \ce{Me\!Me\!Me\!Me}\ce{SO3Na}^- \ce{H}\cdot\ce{SO3^-Na}^- \\
& \xrightarrow{2. \ce{NaCN}} \ce{Me\!Me\!Me\!Me}\ce{HO}\ce{CN} \\
& \text{70% yield}
\end{align*}
\]

Other compounds from cyanohydrins
Cyanohydrins can be converted by simple reactions into hydroxyacids or amino alcohols. Here is one example of each, but you will have to wait until Chapter 10 for the details and the mechanisms of the reactions. Note that one cyanohydrin was made by the simplest method—simply NaCN and acid—while the other came from the bisulfite route we have just discussed.

- hydroxyacids by hydrolysis of CN in cyanohydrin
  \[
  \begin{align*}
  \ce{Ph\!Me\!Me}\ce{O} & \xrightarrow{\text{NaCN, HCl, Et}_2\text{O}} \ce{Ph\!Me\!Me}\ce{HO}\ce{CN} \\
  & \xrightarrow{\text{HCl, H}_2\text{O}} \ce{Ph\!Me\!Me}\ce{HO}\ce{CO_2H}
  \end{align*}
  \]

- amino alcohols by reduction of CN in cyanohydrin
  \[
  \begin{align*}
  \ce{Me\!Me\!Me\!Me}\ce{O} & \xrightarrow{\text{NaCN, H}_2\text{O, NaHSO3}} \ce{Me\!Me\!Me\!Me}\ce{HO}\ce{CN} \\
  & \xrightarrow{\text{LiAlH}_4} \ce{Me\!Me\!Me\!Me}\ce{HO}\ce{NH_2}
  \end{align*}
  \]

The second reason that bisulfite compounds are useful is that they are soluble in water. Some small (that is, low molecular weight) aldehydes and ketones are water-soluble—acetone is an example. But most larger (more than four or so carbon atoms) aldehydes and ketones are not.
This does not usually matter to most chemists as we often want to carry out reactions in organic solvents rather than water. But it can matter to medicinal chemists, who make compounds that need to be compatible with biological systems. And in one case, the solubility of bisulfite adduct in water is literally vital.

Dapsone is an antileprosy drug. It is a very effective one too, especially when used in combination with two other drugs in a ‘cocktail’ that can be simply drunk as an aqueous solution by patients in tropical countries without any special facilities, even in the open air. But there is a problem! Dapsone is insoluble in water. The solution is to make a bisulfite compound from it. You may ask how this is possible since dapsone has no aldehyde or ketone—just two amino groups and a sulfone. The trick is to use the formaldehyde bisulfite compound and exchange the OH group for one of the amino groups in dapsone.

Now the compound will dissolve in water and release dapsone inside the patient. The details of this sort of chemistry will come in Chapter 11, when you will meet imines as intermediates. But at this stage we just want you to appreciate that even the relatively simple chemistry in this chapter is useful in synthesis, in commerce, and in medicine.

Introduction

As you look around you, you will be aware of many different colours—from the greens and browns outside to the bright blues and reds of the clothes you are wearing. All these colours result from the interaction of light with the pigments in these different things—some frequencies of light are absorbed, others scattered. Inside our eyes, chemical reactions detect these different frequencies and convert them into electrical nerve impulses sent to the brain. All these pigments have one thing in common—lots of double bonds. For example, the pigment responsible for the red colour in tomatoes, lycopene, is a long-chain polyalkene.

Lycopene contains only carbon and hydrogen; many pigments contain other elements. But nearly all contain double bonds—and many of them. This chapter is about the properties, including colour, of molecules that have several double bonds. These properties depend on the way the double bonds join up, or conjugate, and the resulting delocalization of the electrons within them.

In earlier chapters we talked about carbon skeletons made up of \( \sigma \) bonds. In this chapter we shall see how, in some cases, we can also have a large \( \pi \) framework spread over many atoms and how this dominates the chemistry of such compounds. We shall see how this \( \pi \) framework is responsible for the otherwise unexpected stability of certain cyclic polyunsaturated
compounds, including benzene, but also reactivity in others, such as butadiene. We shall also see how this $\pi$ framework gives rise to colour. To understand such molecules properly, we need to start with the simplest of all unsaturated compounds, ethene.

**The structure of ethene (ethylene, CH$_2$=CH$_2$)**

The structure of ethene (ethylene) is well known. It has been determined by electron diffraction and is planar (all atoms are in the same plane), with the bond lengths and angles shown on the left. The carbon atoms are roughly trigonal and the C–C bond distance is shorter than that of a typical C–C single bond. The electronic structure of ethene, you will recall from Chapter 4, can be considered in terms of two sp$^2$ hybridized C atoms with a $\sigma$ bond between them and four $\sigma$ bonds linking them each to two H atoms. The $\pi$ bond is formed by overlap of a p orbital on each carbon atom.

*Ethene* is chemically more interesting than *ethane* because of the $\pi$ system. As you saw in Chapter 5, alkenes can be nucleophiles because the electrons in the $\pi$ bond are available for donation to an electrophile. But remember that when we combine two atomic orbitals we get two molecular orbitals, from combining the p orbitals either in phase or out of phase. The in-phase combination accounts for the bonding molecular orbital ($\pi$), whilst the out-of-phase combination accounts for the antibonding molecular orbital ($\pi^*$). The shapes of the orbitals as they were introduced in Chapter 4 are shown below, but in this chapter we will also represent them in the form shown in the brown boxes—as the constituent p orbitals.
Molecules with more than one C=C double bond

Benzene has three strongly interacting double bonds

The rest of this chapter concerns molecules with more than one C=C double bond and what happens to the π orbitals when they interact. To start, we shall take a bit of a jump and look at the structure of benzene. Benzene has been the subject of considerable controversy since its discovery in 1825. It was soon worked out that the formula was C₆H₆, but how were these atoms arranged? Some strange structures were suggested until Kekulé proposed the correct structure in 1865.

Shown below are the molecular orbitals for Kekulé’s structure. As in simple alkenes, each of the carbon atoms is sp² hybridized, leaving the remaining p orbital free.

The σ framework of the benzene ring is like the framework of an alkene, and for simplicity we have just represented the σ bonds as green lines. The difficulty comes with the p orbitals— which pairs do we combine to form the π bonds? There seem to be two possibilities.

With benzene itself, these two forms are identical but, if we had a 1,2- or a 1,3-disubstituted benzene compound, these two forms would be different. A synthesis was designed for the two compounds in the box on the right but it was found that both compounds were identical. This posed a problem to Kekulé—his structure didn’t seem to work after all. His solution—which we now know to be incorrect—was that benzene rapidly equilibrates, or ‘resonates’, between the two forms to give an averaged structure in between the two.

The molecular orbital answer to this problem is that all six p orbitals can combine to form (six) new molecular orbitals, and the electrons in these orbitals form a ring of electron density above and below the plane of the molecule. Benzene does not resonate between the two Kekulé structures—the electrons are in molecular orbitals spread equally over all the carbon atoms. However, the term ‘resonance’ is still sometimes used (but not in this book) to describe the averaging effect of this mixing of molecular orbitals. We shall describe the π electrons in benzene as delocalized, that is, no longer localized in specific double bonds between two particular carbon atoms but spread out, or delocalized, over all six atoms in the ring.
The alternative drawing on the left shows the π system as a ring and does not put in the double bonds: you may feel that this is a more accurate representation, but it does present a problem when it comes to writing mechanisms. As you saw in Chapter 5, the curly arrows we use represent two electrons. The circle here represents six electrons, so in order to write reasonable mechanisms we still need to draw benzene as though the double bonds were localized. However, when you do so, you must keep in mind that the electrons are delocalized, and it does not matter which of the two arrangements of double bonds you draw.

If we want to represent delocalization using these ‘localized’ structures, we can do so using curly arrows. Here, for example, are the two ‘localized’ structures corresponding to 2-bromo-carboxylic acid. The double bonds are not localized, and the relationship between the two structures can be represented with curly arrows which indicate how one set of bonds map onto the other.

These curly arrows are similar to the ones we introduced in Chapter 5, but there is a crucial difference: here, there is no reaction taking place. In a real reaction, electrons move. Here, they do not: the only things that ‘move’ are the double bonds in the structures. The curly arrows just show the link between alternative representations of exactly the same molecule. You must not think of them as showing ‘movement round the ring’. To emphasize this difference we also use a different type of arrow connecting them—a delocalization arrow made up of a single line with an arrow at each end. Delocalization arrows remind us that our simple fixed-bond structures do not tell the whole truth and that the real structure is a mixture of both.

The fact that the π electrons are not localized in alternating double bonds but are spread out over the whole system in a ring is supported by theoretical calculations and confirmed by experimental observations. Electron diffraction studies show benzene to be a regular planar hexagon with all the carbon–carbon bond lengths identical (139.5 pm). This bond length is in between that of a carbon–carbon single bond (154.1 pm) and a full carbon–carbon double bond (133.7 pm). A further strong piece of evidence for this ring of electrons is revealed by proton NMR and discussed in Chapter 13.
How to describe delocalization?

What words should be used to describe delocalization is a vexed question. Terms such as resonance, mesomerism, conjugation, and delocalization are only a few of the ones you will find in books. You will already have noticed that we’re avoiding resonance because it carries a suggestion that the structure is somehow oscillating between localized structures. We shall use the words conjugation and delocalization: conjugation focuses on the way that double bonds link together into a single π system, while delocalization focuses on the electrons themselves. Adjacent double bonds, as you will see, are conjugated; the electrons in them are delocalized.

Multiple double bonds not in a ring

Are electrons still delocalized even when there is no ring? To consider this, we’ll look at hexatriene—three double bonds and six carbons, like benzene, but without the ring. There are two isomers of hexatriene, with different chemical and physical properties, because the central double bond can adopt a cis or a trans geometry. The structures of both cis- and trans-hexatriene have been determined by electron diffraction and two important features emerge:

- Both structures are essentially planar.
- Unlike benzene, the double and single bonds have different lengths, but the central double bond in each case is slightly longer than the end double bonds and the single bonds are slightly shorter than a ‘standard’ single bond.

Here’s the most stable structure of trans-hexatriene, with benzene shown for comparison.

![Diagram of trans-hexatriene and benzene comparison]

The reason for the deviation of the bond lengths from typical values and the preference for planar structures is again due to the molecular orbitals which arise from the combination of the six p orbitals. Just as in benzene, these orbitals can combine to give one molecular orbital stretching over the whole molecule. The p orbitals can overlap and combine only if the molecule is planar.

If the molecule is twisted about one of the single bonds, then some overlap is lost, making it harder to twist about the single bonds in this structure than in a simple alkene. Other planar arrangements are stable, however, and trans-hexatriene can adopt any of the planar conformations shown in the margin.

Conjugation

In benzene and hexatriene every carbon atom is sp² hybridized with one p orbital available to overlap with its neighbours. The uninterrupted chain of p orbitals is a consequence of having alternate double and single bonds. When two double bonds are separated by just one single bond, the two double bonds are said to be conjugated. Conjugated double bonds have different properties from isolated double bonds, both physically (they are often longer, as you have just seen) and chemically (see Chapters 22).

You have already met several conjugated systems: lycopene at the start of this chapter and β-carotene in Chapter 3, for example. Each of the 11 double bonds in β-carotene is separated...
from its neighbour by only one single bond. We again have a long chain in which all the p orbitals can overlap to form molecular orbitals.

β-carotene—all eleven double bonds are conjugated

It is not necessary to have two C=O double bonds in order to have a conjugated system—the C=C and C=O double bonds of propenal (acrolein) are also conjugated. What is important is that the double bonds are separated by one and only one single bond. Here’s a counter-example: arachidonic acid is one of the fabled ‘polyunsaturated’ fatty acids. None of the four double bonds in this structure are conjugated since in between any two double bonds there is an sp³ carbon. This means that there is no p orbital available to overlap with the ones from the double bonds. The saturated carbon atoms ‘insulate’ the double bonds from each other and prevent conjugation.

If an atom has two double bonds directly attached to it, that is, there are no single bonds separating them, again no conjugation is possible. The simplest compound with such an arrangement is allene. The arrangement of the p orbitals in allene means that no delocalization is possible because the two π bonds are perpendicular to each other.

**Requirements for conjugation**
- Conjugation requires double bonds separated by one single bond.
- Double bonds separated by two single bonds or no single bonds are not conjugated.

### The conjugation of two π bonds

To understand the effects of conjugation on molecules, we need now to look at their molecular orbitals. We’ll concentrated only on the electrons in π orbitals—you can take it that all the C–C and C–H σ bonds are essentially the same as those of all the other molecules you met in Chapter 4. We’ll start with the simplest compound that can have two conjugated π bonds: butadiene. As you would expect, butadiene prefers to be planar to maximize overlap between its p orbitals. But exactly how does that overlap happen, and how does it give rise to bonding?

### The molecular orbitals of butadiene

Butadiene has two π bonds, each made up of two p orbitals: a total of four atomic orbitals. We’d therefore expect four molecular orbitals, housing four electrons. Just like
hexatriene above, these orbitals extend over the whole molecule, but we can easily work out what these molecular orbitals look like simply by taking the orbitals of two alkenes and interacting them side by side. We have two π orbitals and two π* orbitals, and we can interact them in phase or out of phase. Here are the first two, made by interacting the two π orbitals:

\[ \text{2 x π orbitals} \]

\[ \text{combine in phase} \]

\[ \text{lowest energy π molecular orbital of butadiene} \]

\[ \text{2 x π orbitals} \]

\[ \text{combine out of phase} \]

\[ \text{second lowest energy π molecular orbital of butadiene} \]

and the next two, made from two π* orbitals:

\[ \text{2 x π* orbitals} \]

\[ \text{combine in phase} \]

\[ \text{second highest energy π molecular orbital of butadiene} \]

\[ \text{2 x π* orbitals} \]

\[ \text{combine out of phase} \]

\[ \text{highest energy π molecular orbital of butadiene} \]

We can represent all four molecular orbitals like this, stacked up in order of their energy in a molecular orbital energy level diagram. With four orbitals, we can’t just use “*” to represent antibonding orbitals, so conventionally they are numbered \( ψ_1–ψ_4 \) (\( ψ \) is the Greek letter psi).

\[ \text{Interactive bonding orbitals in butadiene} \]

It’s worth noticing a couple of other things about the way we have represented these four molecular orbitals before we move on. Firstly, the number of nodes (changes in phase as you move from one orbital to the next) increases from zero in \( ψ_1 \) to three in \( ψ_4 \). Secondly, notice that the p orbitals making up the π system are not all shown as the same size—their coefficients vary according to the orbital they are in. This is a mathematical consequence of the way the orbitals sum together, and you need not be concerned with the details, just the general principle that \( ψ_1 \) and \( ψ_4 \) have the largest coefficients in the middle, \( ψ_2 \) and \( ψ_3 \) the largest coefficients at the ends.

Now for the electrons: each orbital holds two electrons, so the four electrons in the π system go into orbitals \( ψ_1 \) and \( ψ_2 \).
A closer look at these filled orbitals shows that in $\psi_1$, the lowest energy bonding orbital, the electrons are spread out over all four carbon atoms (above and below the plane) in one continuous orbital. There is bonding between all four C atoms—three net bonding interactions. $\psi_2$ has bonding interactions between carbon atoms 1 and 2, and also between 3 and 4 but an antibonding interaction between carbons 2 and 3—in other words, $2 - 1 = 1$ net bonding interaction. For the unoccupied orbitals there is a net $-1$ antibonding interaction in $\psi_3$ and a net $-3$ antibonding interaction in $\psi_4$.

Overall, in both the occupied $\pi$ orbitals there are electrons between carbons 1 and 2 and between 3 and 4, but the antibonding interaction between carbons 2 and 3 in $\psi_2$ partially cancels out the bonding interaction in $\psi_1$. Only ‘partially’, because the coefficients of the antibonding pair of orbitals in $\psi_2$ are smaller than the coefficients of the bonding pair in $\psi_1$. This explains why all the bonds in butadiene are not the same, and also why the middle bond is like a single bond but with a little bit of double-bond character. Its double-bond character extends to its preference for planarity, the fact that it takes more energy to rotate about this bond than about a typical single bond, and the fact that it is slightly shorter (1.45 Å) than a typical C–C single bond (around 1.54 Å).

The molecular orbital diagram also helps us explain some aspects of the reactivity of butadiene. Notice that we have marked on for you the HOMO ($\psi_2$) and the LUMO ($\psi_3$). On either side you can see the equivalent HOMO ($\pi$ orbital) and LUMO ($\pi^*$ orbital) for the isolated alkene (i.e. ethene). Some relevant features to note:

- The overall energy of the two bonding butadiene molecular orbitals is lower than that of the two molecular orbitals for ethene. This means that conjugated butadiene is more thermodynamically stable than just two isolated double bonds.
- The HOMO of butadiene is higher in energy than the HOMO for ethene. This is consistent with the fact that butadiene is more reactive than ethene towards electrophiles.
- The LUMO for butadiene is lower in energy than the LUMO for ethene. This is consistent with the fact that butadiene is more reactive than ethene towards nucleophiles.

So conjugation makes butadiene more stable, but it also makes it more reactive to both nucleophiles and electrophiles! This superficially surprising result is revisited in detail in Chapter 19.

**UV and visible spectra**

In Chapter 2 you saw how, if given the right amount of energy, electrons can be promoted from a low-energy atomic orbital to a higher energy one and how this gives rise to an atomic absorption spectrum. Exactly the same process can occur with molecular orbitals: energy of the right wavelength can promote an electron from a filled orbital (for example the HOMO) to an unfilled one (for example the LUMO), and plotting the absorption of energy against wavelength gives rise to a new type of spectrum called, for obvious reasons which you will see in a moment, a UV–visible spectrum.

You have just seen that the energy difference between the HOMO and LUMO for butadiene is less than that for ethene. We would therefore expect butadiene to absorb light of longer
wavelength than ethene (the longer the wavelength the lower the energy). This is indeed the case: butadiene absorbs at 215 nm compared to 185 nm for ethene. The conjugation in butadiene means it absorbs light of a longer wavelength than ethene. One of the consequences of conjugation is to lessen the gaps between filled and empty orbitals, and so allow absorption of light of a longer wavelength.

- The more conjugated a compound is, the smaller the energy transition between its HOMO and LUMO, and hence the longer the wavelength of light it can absorb. UV–visible spectroscopy can tell us about the conjugation present in a molecule.

Both ethene and butadiene absorb in the UV region of the electromagnetic spectrum. If we extend the conjugation further, the gap between HOMO and LUMO will eventually be small enough to allow the compound to absorb visible light and hence have a colour. Lycopene, the pigment in tomatoes, which we introduced at the start of the chapter, has 11 conjugated double bonds (plus two unconjugated ones). It absorbs blue–green light at about 470 nm; consequently tomatoes are red. Chlorophyll, in the margin, has a cyclic conjugated system: it absorbs at long wavelengths and is green.

The colour of pigments depends on conjugation

It is no coincidence that these and many other highly conjugated compounds are coloured. All dyes and pigments based on organic compounds are highly conjugated.

The table below shows the approximate wavelengths of light absorbed by a polyene conjugated system containing various numbers \(n\) of double bonds. Note that the colour absorbed is complementary to the colour transmitted—a red compound must absorb blue and green light to appear red.

Fewer than about eight conjugated double bonds, and the compound absorbs only in the UV. With more than eight conjugated double bonds, the absorption creeps into the visible and, by the time it reaches 11, the compound is red. Blue or green polyenes are rare, and dyes of these colours rely on more elaborate conjugated systems.
Blue jeans

Transitions from bonding to antibonding π orbitals are called π→π* transitions. If electrons are instead promoted from a non-bonding lone pair (n orbital) to a π* orbital (an n→π* transition) smaller energy gaps may be available, and many dyes make use of n→π* transitions to produce colours throughout the whole spectrum. For example, the colour of blue jeans comes from the pigment indigo. The two nitrogen atoms provide the lone pairs that can be excited into the π* orbitals of the rest of the molecule. These are low in energy because of the two carbonyl groups. Yellow light is absorbed by this pigment and indigo—blue light is transmitted.

Jeans are dyed by immersion in a vat of reduced indigo, which is colourless since the conjugation is interrupted by the central single bond. When the cloth is hung up to dry, the oxygen in the air oxidizes the pigment to indigo and the jeans turn blue.

The allyl system

The allyl anion

In butadiene, four atomic p orbitals interact to make four molecular orbitals; in hexatriene (and you will soon see benzene too) six atomic orbitals interact to make six molecular orbitals. We are now going to consider some common conjugated systems made up of three interacting p orbitals. We’ll start with the structure we get from treating propene with a very strong base—one strong enough to remove one of the protons from its methyl group. H+ is removed, so the product must have a negative charge, which formally resides on the carbon of what was the methyl group. That carbon atom started off sp3 hybridized (i.e. tetrahedral: it had four substituents), but after it has been deprotonated it must become trigonal (sp2), with only three substituents plus a p orbital to house the negative charge.

We could work out the orbitals of the allyl anion by combining this p orbital with a ready-made π bond, but instead this time we will start with the three separate p atomic orbitals and combine them to get three molecular orbitals. At first we are not concerned about where the electrons are—we are just building up the molecular orbitals. The lowest energy orbital (ψ1) will have them all combining in phase. This is a bonding orbital since all the interactions are bonding. The next orbital (ψ2) requires one node, and the only way to include a node and maintain the symmetry of the system is to put the node through the central atom. This means that when this orbital is occupied there will be no electron density on this central atom. Since there are no interactions between adjacent atomic orbitals (either bonding or antibonding), this is a non-bonding orbital. The final molecular
orbital ($\psi_3$) must have two nodal planes. All the interactions of the atomic orbitals are out of phase so the resulting molecular orbital is an antibonding orbital.

We can summarize all this information in a molecular orbital energy level diagram, and at the same time put the electrons into the orbitals. We need four electrons—two from the alkene $\pi$ bond and two more for the anion (these were the two in the C–H bond, and they are still there because only a proton, $H^+$, was removed). The four electrons go into the lowest two orbitals, $\psi_1$ and $\psi_2$, leaving $\psi_3$ vacant. Notice too that the energy of two of the electrons is lower than it would have been if they had remained in unconjugated $p$ orbitals: conjugation lowers the energy of filled orbitals and makes compounds more stable.

Where is the electron density in the allyl anion $\pi$ system? We have two filled $\pi$ molecular orbitals and the electron density comes from a sum of both orbitals. This means there is electron density on all three carbon atoms. However, the coefficients of the end carbons are of a significant size in both orbitals, but in $\psi_2$ the middle carbon has no electron density at all—it lies on a node. So overall, even though the negative charge is spread over the whole molecule, the end carbons carry more of the electron density than the middle one. We can represent this in two ways—the first structure below emphasizes the delocalization of the charge over the whole molecule, but fails to get across the important point that the negative charge resides principally at the ends. Curly arrows do this much better: we can use them to show that the negative charge is not localized, but principally divided between the two end carbons.
The problem with these structures carrying curly arrows is that they seem to imply that the negative charge (and the double bond for that matter) is jumping from one end of the molecule to the other. This, as we have seen, is just not so. Another and perhaps better picture uses dotted lines and partial charges. But the structure with the dotted bonds, as with the representation of benzene with a circle in the middle, is no good for writing mechanisms. Each of the representations has its strong and weak points: we shall use each as the occasion demands.

Using NMR to study delocalization

Delocalization of the alkyl anion, and the localization of the negative charge mainly on the end carbons, is clear from its $^{13}$C NMR spectrum as well. In Chapter 3 we explained that $^{13}$C NMR gives us a good measure of the amount of electron density around a C atom—the extent to which it is deshielded and therefore exposed to the applied magnetic field. If you need reminding about the terminology, theory, and practice of NMR, turn back now to Chapter 3, pp. 52–63.

It is possible to record a $^{13}$C NMR spectrum of an allyl anion with a lithium counterion. The spectrum shows only two signals: the middle carbon at 147 ppm and the two end carbons both at 51 ppm. This confirms two things: (i) both end carbons are the same and the structure is delocalized, and (ii) most of the negative charge is on the end carbons—they are more shielded (have a smaller chemical shift) as a result of the greater electron density. In fact, the central carbon’s shift of 147 ppm is not far from that of a normal double-bond carbon (compare the signals in propene). The end carbons’ shift is in between that of a double bond and a saturated carbon directly bonded to a metal (e.g. methyl lithium, whose negative chemical shift results from the highly polarized Li–C bond).

The allyl cation

What if, instead of taking just a proton, we had also taken away two electrons from propene? In reality we can get such a structure quite straightforwardly from allyl bromide (prop-2-enyl bromide or 1-bromoprop-2-ene). Carbon 1 in this compound has four atoms attached to it (a carbon, two hydrogens, and a bromine atom) so it is tetrahedral (or sp$^3$ hybridized).

Bromine is more electronegative than carbon and so the C–Br bond is polarized towards the bromine. It is quite easy to break this bond completely, with the bromine keeping both electrons from the C–Br bond to become bromide ion, Br$^-$, leaving behind an allyl cation. The positively charged carbon now has only three substituents so it becomes trigonal (sp$^2$ hybridized). It must therefore have a vacant p orbital.

Like the allyl anion, the orbitals in the allyl cation are a combination of three atomic p orbitals, one from each carbon. So we can use the same molecular orbital energy level diagram as we did for the anion, simply by adjusting the number of electrons we put into the orbitals. This time, there are only two electrons, from the alkene, as those which were in the C–Br bond have left with anionic bromide.
The two electrons in the filled orbital are in a lower energy orbital than they would have been if they had stayed in an unconjugated p orbital: as with the anion, \emph{conjugation} leads to \emph{stabilization}.

The two electrons are spread over three carbon atoms. Overall, the allyl cation has a positive charge. But where is the positive charge concentrated? What we need to do is look to see where there is a \emph{deficit} of charge. The only orbital with any electrons in it is the bonding molecular orbital $\psi_1$. From the relative sizes of the coefficients on each atom we can see that the middle carbon has more electron density on it than the end ones, so the end carbons must be more positive than the middle one.

We expect both end carbons to be identical, and $^{13}$C NMR tells us that this is so (see below). Again we need a way of showing this delocalization, either on a single structure or as a pair of localized structures linked by a delocalization arrow.

Notice how we draw the curly arrows here: we want to show the positive charge ‘moving’, and it is tempting to draw a curly arrow starting from the positive charge. But curly arrows must always start on something representing a pair of electrons. So we must move the positive charge as a consequence of the movement of the electrons in the double bond: as we pull them away from one end, they leave behind a positive charge.

**The NMR spectrum of a delocalized cation**

The reaction below shows the formation of a cation close in structure to the allyl cation. A very strong acid (called ‘super-acid’—see Chapter 15) protonates the OH group of 3-cyclohexenol, which can then leave as water. The resulting cation is, not surprisingly, unstable and would normally react rapidly with a nucleophile. However, at low temperatures and if there are no nucleophiles present, the cation is relatively stable and it is even possible to record a $^{13}$C NMR spectrum (at $-80 \, ^\circ$C).

The $^{13}$C NMR spectrum of this allylic cation reveals a plane of symmetry, which confirms that the positive charge is spread over two carbons. The large shift of 224 ppm for these carbons indicates very strong deshielding (that is, lack of electrons) but is nowhere near as large as that of a localized cation (which would resonate at about 330 ppm). The middle carbon’s shift of 142 ppm is almost typical of a normal double bond, indicating that it is neither significantly more nor less electron-rich than normal. In fact, it is interesting to note that the middle carbon of this cation and the allyl anion we described above have almost exactly the same chemical shift—proof that the charge lies mainly on the ends of the allyl system.
Delocalization over three atoms is a common structural feature

The carboxylate anion

You may already be familiar with one anion very much like the allyl anion—the carboxylate ion, which forms when a carboxylic acid reacts with a base. In this structure we again have a negatively charged atom separated from a double bond by a single bond adjacent to a single bond: it’s analogous to an allyl anion with oxygen atoms replacing two of the carbon atoms.

\[
\begin{align*}
\text{a carboxylic acid} & \quad \xrightarrow{\text{rearrangement}} \quad \text{a carboxylate anion} \\
& \quad \text{compare with the allyl anion:}
\end{align*}
\]

X-ray crystallography shows both carbon–oxygen bond lengths in this anion to be the same (136 pm), in between that of a normal carbon–oxygen double bond (123 pm) and single bond (143 pm). The negative charge is spread out equally over the two oxygen atoms, and we can represent this in two ways—as before, the one on the left shows the equivalence of the two C–O bonds, but you would use the one on the right for writing mechanisms. The delocalization arrow tells us that both localized forms contribute to the real structure.

The nitro group

The nitro group consists of a nitrogen bonded to two oxygen atoms and a carbon (for example an alkyl group). There are two ways of representing the structure: one using formal charges, the other (which we suggest you avoid) using a dative bond. Notice in each case that one oxygen is depicted as being doubly bonded, the other singly bonded. Drawing both oxygen atoms doubly bonded is incorrect—nitrogen cannot participate in five bonds: this would require ten bonding electrons around the N atom, and there are not enough s and p orbitals to put them in.

\[
\begin{align*}
\text{two ways of representing the nitro group}
\end{align*}
\]

The problem even with the ‘correct’ structure on the left is that the equivalence of the two N–O bonds is not made clear. The nitro group has exactly the same number of electrons as a carboxylate anion (although it’s neutral of course because nitrogen already has one more electron than carbon) and the delocalized structure can be shown with curly arrows in the same way.

We have not shown molecular orbital energy level diagrams for the carboxylate and nitro groups, since they are similar to that of the allyl anion. Only the absolute energies of the molecular orbitals are different since different elements with different electronegativities are involved in each case.

The amide group

Life is built of amides, because the amide group is the link through which amino acids join together to form the proteins which make up much of the structural features of living systems.
Nylon is a synthetic polyamide, and shares with many proteins the property of durability. The structure of this deceptively simple functional group has an unexpected feature which is responsible for much of the stability it confers.

The allyl anion, carboxylate, and nitro groups have four electrons in a $\pi$ system spread out over three atoms. The nitrogen in the amide group also has a pair of electrons that can conjugate with the $\pi$ bond of the carbonyl group. For effective overlap with the $\pi$ bond, this lone pair of electrons must be in a p orbital. This in turn means that the nitrogen must be sp$^2$ hybridized.

In the carboxylate ion, a negative charge is shared (equally) between two oxygen atoms. In an amide there is no charge as such—the lone pair on nitrogen is shared between the nitrogen and the oxygen. The delocalization can be shown as usual by using curly arrows, as shown in the margin.

This representation suffers from the usual problems. Curly arrows usually show electron movement, but here they do not: they simply show how to get from one of the alternative representations to the other. The molecular orbital picture of the amide tells us that the electrons are unevenly distributed over the three atoms in the $\pi$ system with a greater electron density on the oxygen: you can see this in the delocalized structure on the right, which has a full negative charge on O and a positive charge on N. (We also indicated this in the diagram of the lowest energy $\pi$ orbital above, which has a greatest coefficient, and therefore greatest electron density, on O.) Another aspect of the structure of the amide group that this pair of structures indicates correctly is that there is partial double bond character between the C atom and the N atom. We will come back to this shortly.

The real structure of the amide group lies in between the two extreme structures linked by the delocalization arrow: a better representation might be the structure on the right. The charges in brackets indicate substantial, although not complete, charges, maybe about a half plus or minus charge. However, we cannot draw mechanisms using this structure.

We can summarize several points about the structure of the amide group, and we will then return to each in a little more detail:

- The amide group is planar—this includes the first carbon atoms of the R groups attached to the carbonyl group and to the nitrogen atom.
- The lone pair of electrons on nitrogen is delocalized into the carbonyl group.
- The C–N bond is strengthened by this interaction—it takes on partial double bond character. This also means that we no longer have free rotation about the C–N bond, which we would expect if it were only a single bond.
- The oxygen is more electron-rich than the nitrogen. Hence we might expect the oxygen rather than the nitrogen to be the site of electrophilic attack.
- The amide group as a whole is made more stable as a result of the delocalization.

How do we know the amide group is planar? X-ray crystal structures are the simplest answer. Other techniques such as electron diffraction also show that simple (non-crystalline) amides have planar structures. N,N-Dimethylformamide (DMF) is an example.

The N–CO bond length in DMF (135 pm) is closer to that of a standard C–N double bond (127 pm) than to that of a single bond (149 pm). This partial double bond character, which the delocalized structures led us to expect, is responsible for restricted rotation about this C–N bond. We must supply 88 kJ mol$^{-1}$ if we want to rotate the C–N bond in DMF (remember a single bond only takes about 3 kJ mol$^{-1}$, while a full C–C double bond takes about 260 kJ mol$^{-1}$). The amount of energy available at room temperature is only enough to allow this bond
to rotate slowly, and the result is quite clear in the \(^{13}\text{C}\) NMR spectrum of DMF. There are three carbon atoms altogether and three signals appear—the two methyl groups on the nitrogen are different. If free rotation were possible about the C–N bond, we would expect to see only two signals, since the two methyl groups would become identical.

In fact, if we record the spectrum at higher temperatures, we do indeed only see two signals since now there is sufficient energy available to overcome the rotational barrier and allow the two methyl groups to interchange.

**Amides in proteins**

Proteins are composed of many amino acids joined together with amide bonds. The amino group of one can combine with the carboxylic acid group of another to give an amide known as a peptide—two amino acids join to form a dipeptide; many join to give a polypeptide.

The peptide unit so formed is a planar, rigid structure because of restricted rotation about the C–N bond. This rigidity confers organizational stability on protein structures.

**Conjugation and reactivity: looking forward to Chapter 10**

Just as delocalization stabilizes the allyl cation and anion (at least some of the electrons in conjugated systems end up in lower energy orbitals than they would have done without conjugation) so too is the amide group stabilized by the conjugation of the nitrogen’s lone pair with the carbonyl group. This makes an amide C=O one of the least reactive carbonyl groups (we shall discuss this in Chapter 10). Furthermore, the nitrogen atom of an amide group is very different from that of a typical amine. Most amines are easily protonated. However, since the lone pair on the amide’s nitrogen is conjugated into the \(\pi\) system, it is less available for protonation or, indeed, reaction with any electrophile. As a result, when an amide is protonated (and it is not protonated easily, as you will see in the next chapter) it is protonated on oxygen rather than nitrogen. The consequences of conjugation for reactivity extend far and wide, and will be a running theme through many chapters in this book.

**Aromaticity**

It’s now time to go back to the structure of benzene. Benzene is unusually stable for an alkene and is not normally described as an alkene at all. For example, whereas normal alkenes (whether conjugated or not) readily react with bromine to give dibromoalkane addition products, benzene reacts with bromine only with difficulty—it needs a catalyst (iron will do) and then the product is a monosubstituted benzene and not an addition compound.
Bromine reacts with benzene in a substitution reaction (a bromine atom replaces a hydrogen atom), *keeping the benzene structure intact*. This ability to retain its conjugated structure through all sorts of chemical reactions is one of the important differences between benzene and other alkenes.

**What makes benzene special?**

You might assume benzene’s special feature is its ring structure. To see whether this is the case, we’ll look at another cyclic polyene, cyclooctatetraene, with four double bonds in a ring. Given what we have explained about the way that π systems gain stability by allowing overlap between their p orbitals, you may be surprised to find that cyclooctatetraene, unlike benzene, is not planar. There is no conjugation between any of the double bonds—there are indeed alternate double and single bonds in the structure, but conjugation is possible only if the p orbitals of the double bonds can overlap and here they do not. The fact that there is no conjugation is shown by the alternating C–C bond lengths in cyclooctatetraene—146.2 and 133.4 pm—which are typical for single and double C–C bonds. If possible, make a model of cyclooctatetraene for yourself—you will find the compound naturally adopts the shape on the right below. This shape is often called a ‘tub’.

![cyclooctatetraene](image)

Chemically, cyclooctatetraene behaves like an alkene, not like benzene. With bromine, for example, it forms an addition product and not a substitution product. So benzene is not special just because it is cyclic—cyclooctatetraene is cyclic too but does not behave like benzene.

**Heats of hydrogenation of benzene and cyclooctatetraene**

C=C double bonds can be reduced using hydrogen gas and a metal catalyst (usually nickel or palladium) to produce fully saturated alkanes. This process is called hydrogenation and it is exothermic (that is, energy is released) since a thermodynamically more stable product, an alkane, is produced.

When cis-cyclooctene is hydrogenated to cyclooctane, 96 kJ mol⁻¹ of energy is released. Cyclooctatetraene releases 410 kJ mol⁻¹ on hydrogenation. This value is approximately four times one double bond’s worth, as we might expect. However, whereas the heat of hydrogenation for cyclohexene is 120 kJ mol⁻¹, on hydrogenating benzene only 208 kJ mol⁻¹ is given out, which is much less than the 360 kJ mol⁻¹ that we would have predicted by multiplying the figure for cyclohexene by 3. Benzene has something to make it stable which cyclooctatetraene does not have.
Varying the number of electrons

The mystery deepens when we look at what happens when we treat cyclooctatetraene with powerful oxidizing or reducing agents. If 1,3,5,7-tetramethylcyclooctatetraene is treated at low temperature (–78 °C) with SbF₅/SO₂ClF (strongly oxidizing conditions) a dication is formed. This cation, unlike the neutral compound, is planar and all the C–C bond lengths are the same.

\[ \text{Me} \quad \text{Me} \quad \text{Me} \quad \text{Me} \]
\[ \text{H} \quad \text{H} \quad \text{H} \quad \text{H} \]
\[ \text{SbF}_5, \text{SO}_2\text{ClF} \]
\[ \text{H}_2 \quad \text{H}_2 \]
\[ \Delta H \text{cyclooctatetraene} \]
\[ 410 \text{ kJ mol}^{-1} \]
\[ \Delta H \text{cyclohexene} \]
\[ 120 \text{ kJ mol}^{-1} \]
\[ \text{H}_2 + \]
\[ \Delta H \text{cyclooctene} \]
\[ 96 \text{ kJ mol}^{-1} \]
\[ + 3\text{H}_2 \]
\[ \Delta H \text{benzene} \]
\[ 208 \text{ kJ mol}^{-1} \]

It is also possible to add electrons to cyclooctatetraene by treating it with alkali metals and a dianion results. X-ray structures reveal this dianion to be planar, again with all C–C bond lengths the same (140.7 pm). The difference between the anion and cation of cyclooctatetraene on the one hand and cyclooctatetraene on the other is the number of electrons in the \( \pi \) system. Neutral, non-planar, cyclooctatetraene has eight \( \pi \) electrons, the planar dication has six \( \pi \) electrons (as does benzene), and the planar anion has ten.

Can you see a pattern forming? The important point is not the number of conjugated atoms but the number of electrons in the \( \pi \) system.

- When they have four or eight \( \pi \) electrons, both six- and eight-membered rings adopt non-planar structures; when they have six or ten \( \pi \) electrons, a planar structure is preferred.

If you made a model of cyclooctatetraene, you might have tried to force it to be flat. If you managed this you probably found that it didn’t stay like this for long and that it popped back into the tub shape. The strain in planar cyclooctatetraene can be overcome by the molecule...
adopting the tub conformation. The strain is due to the numbers of atoms and double bonds in the ring—it has nothing to do with the number of electrons. The planar dication and dianion of cyclooctatetraene still have this strain. The fact that these ions do adopt planar structures must mean there is some other form of stabilization that outweighs the strain of being planar. This extra stabilization is called aromaticity.

**Benzene has six π molecular orbitals**

The difference between the amount of energy we expect to get from benzene on hydrogenation (360 kJ mol⁻¹) and what is observed (208 kJ mol⁻¹) is about 150 kJ mol⁻¹. This represents a crude measure of just how extra stable benzene really is relative to what it would be like with three localized double bonds. In order to understand the origin of this stabilization, we must look at the molecular orbitals. We can think of the π molecular orbitals of benzene as resulting from the combination of the six p orbitals in a ring and, as with butadiene, each successively higher energy orbital contains one more node. This is what we get for benzene:

The molecular orbital lowest in energy, ψ₁, has no nodes, with all the orbitals combining in phase. The next lowest molecular orbital will have one nodal plane, which can be arranged in two ways depending on whether or not the nodal plane passes through a bond or an atom. It turns out that these two different molecular orbitals both have exactly the same energy, that is, they are degenerate, and we call them both ψ₂. There are likewise two ways of arranging two nodal planes and again there are two degenerate molecular orbitals ψ₃. The final molecular orbital ψ₄ will have three nodal planes, which must mean all the p orbitals combining out of phase. Six electrons slot neatly into the three lowest energy bonding orbitals.

**The π molecular orbitals of other conjugated cyclic hydrocarbons**

Notice that the layout of the energy levels in benzene is a regular hexagon with its apex pointing downwards. It turns out that the energy level diagram for the molecular orbitals resulting from the combination of any regular cyclic arrangement of p orbitals can be deduced from the appropriately sided polygon with an apex pointing downwards. The horizontal diameter (the red line) represents the energy of a carbon p orbital and any energy levels on this line represent non-bonding molecular orbitals. All molecular orbitals with energies below this line are bonding; all those above are antibonding.
It's worth noting a few points about these energy level diagrams:

- The method predicts the energy levels for the molecular orbitals of planar, cyclic arrangements of identical atoms (usually all C) only.
- There is always one single molecular orbital lower in energy than all the others. This is because there is always one molecular orbital where all the p orbitals combine in phase.
- If there is an even number of atoms, there is also a single molecular orbital highest in energy; otherwise there will be a pair of degenerate molecular orbitals highest in energy.
- All the molecular orbitals come in degenerate pairs except the one lowest in energy and (for even-numbered systems) the one highest in energy.

Molecular orbitals and aromaticity

Now we can begin to put all the pieces together and make sense of what we know so far. We'll compare the way that the electrons fit into the energy level diagrams for benzene and planar cyclooctatetraene. We are not concerned with the actual shapes of the molecular orbitals involved, just their energies.

Benzene has six π electrons, which means that all its three bonding molecular orbitals are fully occupied, giving what we can call a ‘closed shell’ structure. Cyclooctatetraene’s eight electrons, on the other hand, do not fit so neatly into its orbitals. Six of these fill up the bonding molecular orbitals but there are two electrons left. These must go into the degenerate pair of non-bonding orbitals. Hund’s rule (Chapter 4) would suggest one in each. Planar cyclooctatetraene would not have the closed shell structure that benzene has—to get one it must either lose or gain two electrons. This is exactly what we have already seen—both the dianion and dication from cyclooctatetraene are planar, allowing delocalization all over the ring, whereas neutral cyclooctatetraene avoids the unfavourable arrangement of electrons shown below by adopting a tub shape with localized bonds.
Hückel's rule tells us if compounds are aromatic

As we pointed out on the previous page, all the cyclic conjugated hydrocarbons have a single lowest energy molecular orbital, and then a stack of degenerate pairs of orbitals of increasing energy. Since the single low energy orbital holds two electrons, and then the successive degenerate pairs four each, a 'closed shell' arrangement in which all the orbitals below a certain level are filled will always contain \((4n + 2)\) electrons (where \(n\) is an integer—0, 1, 2, etc.—corresponding to the number of degenerate orbital pairs). This is the basis of Hückel's rule.

**Hückel's rule**

Planar, fully conjugated, monocyclic systems with \((4n + 2)\) \(\pi\) electrons have a closed shell of electrons all in bonding orbitals and are exceptionally stable. Such systems are said to be aromatic.

Analogous systems with \(4n\) \(\pi\) electrons are described as anti-aromatic.

The next \((4n + 2)\) number after six is ten so we might expect this cyclic alkene, \([10]\)annulene, to be aromatic. But if a compound with five cis double bonds were planar, each internal angle would be 144°. Since a normal double bond has bond angles of 120°, this would be far from ideal. This compound can be made but it does *not* adopt a planar conformation and therefore is not aromatic even though it has ten \(\pi\) electrons.

By contrast, \([18]\)annulene, which is also a \((4n + 2)\) \(\pi\) electron system \((n = 4)\), does adopt a planar conformation and *is* aromatic. The *trans–trans–cis* double bond arrangement allows all bond angles to be 120°. \([20]\)Annulene presumably could become planar (it isn’t quite) but since it is a \(4n\) \(\pi\) electron system rather than a \(4n + 2\) system, it is not aromatic and the structure shows localized single and double bonds.

When the conjugated systems are not monocyclic, the situation becomes a little less clear. Naphthalene, for example, has ten electrons but you can also think of it as two fused benzene rings. From its chemistry, it is very clear that naphthalene has aromatic character (it does substitution reactions) but is less aromatic than benzene itself. For example, naphthalene can easily be reduced to tetralin (1,2,3,4-tetrahydronaphthalene), which still contains a benzene ring. Also, in contrast to benzene, all the bond lengths in naphthalene are not the same. 1,6-Methano\([10]\)annulene is rather like naphthalene but with the middle bond replaced by a methylene bridging group. This compound is almost flat and shows aromatic character.

Hückel’s rule helps us predict and understand the aromatic stability of numerous other systems. Cyclopentadiene, for example, has two conjugated double bonds but the conjugated system is not cyclic since there is an sp\(^3\) carbon in the ring. However, this compound is relatively easy to deprotonate to give a very stable anion in which all the bond lengths are the same.
Each of the double bonds contributes two electrons and the negative charge (which must be in a p orbital to complete the conjugation) contributes a further two, making six altogether. The energy level diagram shows that six π electrons completely fill the bonding molecular orbitals, thereby giving a stable aromatic structure.

**Heterocyclic aromatic compounds**

So far all the aromatic compounds you have seen have been hydrocarbons. However, most aromatic systems are heterocyclic—that is, they contain atoms other than just carbon and hydrogen. (In fact the majority of all organic compounds are aromatic heterocycles!) A simple example is pyridine, in which a nitrogen replaces one of the CH groups of benzene. The ring still has three double bonds and thus six π electrons.

Consider the structure shown on the left, pyrrole. This is also aromatic but it’s not enough just to use the electrons in the double bonds: in pyrrole the nitrogen’s lone pair contributes to the six π electrons needed for the system to be aromatic. Aromatic chemistry makes several more appearances in this book: in Chapter 21 we shall look at the chemistry of benzene and in Chapters 30 and 31 we shall discuss heterocyclic aromatic compounds in much more detail.

**Further reading**

**Check your understanding**

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Acidity, basicity, and $pK_a$

Organic compounds are more soluble in water as ions

Most organic compounds are insoluble in water. But sometimes it’s necessary to make them dissolve, perhaps by converting them to anions or cations. Water can solvate both cations and anions, unlike some of the solvents you will meet later. A good way of dissolving an organic acid is to put it in basic solution: the base deprotonates the acid to give an anion. A simple example is aspirin: whilst the acid itself is not very soluble in water, the sodium salt is much more soluble. The sodium salt forms with the weak base, sodium hydrogencarbonate.

![Aspirin structure](image)

The sodium or calcium salt of ‘normal’ aspirin is sold as ‘soluble aspirin’. But when the pH of a solution of aspirin’s sodium salt is lowered, the amount of the ‘normal’ acidic form present increases and the solubility decreases. In the acidic environment of the stomach (around pH 1–2), soluble aspirin will be converted back to the normal acidic form and precipitate out of solution.

Water is special for many reasons, and it falls into a class of solvents we call polar protic solvents. We will discuss other solvents in this class, as well as polar aprotic solvents (such as acetone and DMF) and non-polar solvents (such as toluene and hexane) in Chapter 12.
In the same way, organic bases such as amines can be dissolved by lowering the pH. Codeine (7,8-didehydro-4,5-epoxy-3-methoxy-17-methylmorphinan-6-ol) is a commonly used painkiller. Codeine itself is not very soluble in water but it does contain a basic nitrogen atom that can be protonated to give a more soluble salt. It is usually encountered as a phosphate salt. The structure is complex, but that doesn’t matter.

**Charged compounds can be separated by acid–base extraction**

Adjusting the pH of a solution often provides an easy way to separate compounds. Separating a mixture of benzoic acid (PhCO₂H) and toluene (PhMe) is easy: dissolve the mixture in CH₂Cl₂, add aqueous NaOH, shake the mixture of solutions, and separate the layers. The CH₂Cl₂ layer contains all the toluene. The aqueous layer contains the sodium salt of benzoic acid. Addition of HCl to the aqueous layer precipitates the insoluble benzoic acid.

A more realistic separation is given in a modern practical book after a Cannizzaro reaction. You will meet this reaction in Chapters 26 and 39 but all you need to know now is that there are two products, formed in roughly equal quantities. Separation of these from starting material and solvent, as well as from each other, makes this a useful reaction.

The products under the basic reaction conditions are the salt of the acid (soluble in water) and the alcohol (not soluble in water). Extraction with dichloromethane removes the alcohol and leaves the salt in the aqueous layer along with solvent methanol and residual KOH. Rotary evaporation of the CH₂Cl₂ layer gives crystalline alcohol and acidification of the aqueous layer precipitates the neutral acid.
In the same way, any basic compounds dissolved in an organic layer can be extracted by washing the layer with dilute aqueous acid and recovered by raising the pH, which will precipitate out the less soluble neutral compound. A general way to make amines is by ‘reductive amination.’ Ignore the details of this reaction for now (we come back to them in Chapter 11) but consider how the amine might be separated from starting material, by-products, and solvent.

As the reaction mixture is weakly acidic, the amine will be protonated and will be soluble in water. The starting material and intermediate (of which very little is present anyway) are soluble in organic solvents. Extracting the aqueous layer and neutralizing with NaOH gives the amine.

Whenever you do any extractions or washes in practical experiments, just stop and ask yourself: ‘What is happening here? In which layer is my compound and why?’ You will then be less likely to throw away the wrong layer (and your precious compound)!

**Acids, bases, and pKₐ**

If we are going to make use of the acid–base properties of compounds as we have just described, we are going to need a way of measuring how acidic or how basic they are. Raising the pH leads to deprotonation of aspirin and lowering the pH leads to protonation of codeine, but how far do we have to raise or lower the pH to do this? The measure of acidity or basicity we need is called pKₐ. The value of pKₐ tells us how acidic (or not) a given hydrogen atom in a compound is. Knowing about pKₐ tells us, for example, that the amine product from the reaction just above will be protonated at weakly acidic pH 5, or that only a weak base (sodium hydrogen carbonate) is needed to deprotonate a carboxylic acid such as aspirin. It is also useful because many reactions proceed through protonation or deprotonation of one of the reactants (you met some examples in Chapter 6), and it is obviously useful to know what strength acid or base is needed. It would be futile to use too weak a base to deprotonate a compound but, equally, using a very strong base where a weak one would do risks the result of cracking open a walnut with a sledge hammer.

The aim of this chapter is to help you to understand why a given compound has the pKₐ that it does. Once you understand the trends involved, you should have a good feel for the pKₐ values of commonly encountered compounds and also be able to predict roughly the values for unfamiliar compounds.

**Benzoic acid preserves soft drinks**

Benzoic acid is used as a preservative in foods and soft drinks (E210). Like acetic acid, it is only the acid form that is effective as a bactericide. Consequently, benzoic acid can be used as a preservative only in foodstuffs with a relatively low pH, ideally less than its pKₐ of 4.2. This isn’t usually a problem: soft drinks, for example, typically have a pH of 2–3. Benzoic acid is often added as the sodium salt (E211), perhaps because this can be added to the recipe as a concentrated solution in water. At the low pH in the final drink, most of the salt will be protonated to give benzoic acid proper, which presumably remains in solution because it is so dilute.

**Acidity**

Let’s start with two simple, and probably familiar, definitions:

- An acid is a species having a tendency to lose a proton.
- A base is a species having a tendency to accept a proton.
An isolated proton is extremely reactive—formation of $\text{H}_3\text{O}^+$ in water

Gaseous HCl is not an acid at all—it shows no tendency to dissociate into $\text{H}^+$ and $\text{Cl}^-$ as the $\text{H}$–$\text{Cl}$ bond is strong. But hydrochloric acid—that is, a solution of HCl in water—is a strong acid. The difference is that an isolated proton $\text{H}^+$ is too unstable to be encountered under normal conditions, but in water the hydrogen of HCl is transferred to a water molecule and not released as a free species.

The chloride anion is the same in both cases: the only difference is that a very unstable naked proton would have to be the other product in the gas phase but a much more stable $\text{H}_3\text{O}^+$ cation would be formed in water. In fact it’s even better than that, as other molecules of water cluster round (‘solvate’) the $\text{H}_3\text{O}^+$ cation, stabilizing it with a network of hydrogen bonds.

That is why HCl is an acid in water. But how strong an acid is it? This is where chloride plays a role: hydrochloric acid is a strong acid because chloride ion is a stable anion. The sea is full of it! Water is needed to reveal the acidic quality of HCl, and acidity is determined in water as the standard solvent. If we measure acidity in water, what we are really measuring is how much our acid transfers a proton to a water molecule.

HCl transfers its proton almost completely to water, and is a strong acid. But the transfer of protons to water from carboxylic acids is only partial. That is why carboxylic acids are weak acids. Unlike the reaction of HCl with water, the reaction below is an equilibrium.

The pH scale and $pK_a$

The amount of $\text{H}_3\text{O}^+$ in any solution in water is described using the pH scale. pH is simply a measure of the concentration of $\text{H}_3\text{O}^+$ on a logarithmic scale, and it is characteristic of any aqueous acid—it depends not only on what the acid is (hydrochloric, acetic, etc.) but also on how concentrated the acid is.

\[ \text{pH} = -\log[\text{H}_3\text{O}^+] \]

You will already know that neutrality is pH 7 and that below pH 7 water is increasingly acidic while above pH 7 it is increasingly basic. At higher pH, there is little $\text{H}_3\text{O}^+$ in the solution and more hydroxide ion, but at lower pH there is more $\text{H}_3\text{O}^+$ and little hydroxide.

The reason that higher pH means less $\text{H}_3\text{O}^+$ is because the arbitrary definition of pH is the negative logarithm (to the base 10) of the $\text{H}_3\text{O}^+$ concentration. To summarize in a diagram:
pH is used to measure the acidity of aqueous solutions, but what about the inherent tendency of an acidic compound to give up $H^+$ to water and form these acid solutions? A good way of measuring this tendency is to find the pH at which a solution contains exactly the same amount of the protonated, acidic form and its deprotonated, basic form. This number, which is characteristic of any acid, is known as the $pK_a$. In the example just above, this would be the pH where the amount of the carboxylic acid is matched by the amount of its carboxylate salt—which happens to be at about pH 5: the $pK_a$ of acetic acid is 4.76.

We'll come back to a more formal definition of $pK_a$ later, but first we need to look more closely at this pair of species—the protonated acid and its deprotonated, basic partner.

**Every acid has a conjugate base**

Looking back at the equilibrium set up when acetic acid dissolves in water, but drawing the mechanism of the back reaction, we see acetate ion acting as a base and $H_3O^+$ acting as an acid. In all equilibria involving just proton transfer a species acting as a base on one side acts as an acid on the other. We describe $H_3O^+$ as the conjugate acid of water and water as the conjugate base of $H_3O^+$. In the same way, acetic acid is the conjugate acid of acetate ion and acetate ion is the conjugate base of acetic acid.

![Conjugate Acid-Base Pair](image)

For any acid and any base:

$$BH + A^- \rightleftharpoons BH^+ + A^0$$

$AH$ is an acid and $A^-$ is its conjugate base and $B$ is a base and $BH^+$ is its conjugate acid. That is, every acid has a conjugate base associated with it and every base has a conjugate acid associated with it.

Water doesn't have to be one of the participants—if we replace water in the reaction we have been discussing with ammonia, we now have ammonia as the conjugate base of $NH_4^+$ (the ammonium cation) and the ammonium cation as the conjugate acid of ammonia. What is different is the position of equilibrium: ammonia is more basic than water and now the equilibrium will be well over to the right. As you will see, $pK_a$ will help us assess where equilibria like these lie.

![Conjugate Acid-Base Pair](image)

The amino acids you met in Chapter 2 have carboxylic acid and amine functional groups within the same molecule. When dissolved in water, they transfer a proton from the $CO_2H$ group to the $NH_2$ group and form a zwitterion. This German term describes a double ion having positive and negative charges in the same molecule.

![Zwitterion](image)

**Water can behave as an acid or as a base**

So far we have seen water acting as a (very weak) base to form $H_3O^+$. If we added a strong base, such as sodium hydride, to water, the base would deprotonate the water to give hydroxide ion,
HO−, and here the water would be acting as an acid. It’s amusing to notice that hydrogen gas is the conjugate acid of hydride ion, but more important to note that hydroxide ion is the conjugate base of water.

Water is a weak acid and a weak base so we need a strong acid like HCl to give much H3O+, and a strong base, like hydride ion, to give much hydroxide ion.

The ionization of water

The concentration of H3O+ ions in water is very low indeed at 10−7 mol dm−3. Pure water at 25 °C therefore has a pH of 7.00. Hydronium ions in pure water can arise only from water protonating (and deprotonating) itself. One molecule of water acts as a base, deprotonating another that acts as an acid. For every H3O+ ion formed, a hydroxide ion must also be formed, so that in pure water at pH 7 the concentrations of H3O+ and hydroxide ions must be equal:

\[ [\text{H}_3\text{O}^+] = [\text{HO}^-] = 10^{-7} \text{ mol dm}^{-3}. \]

The product of these two concentrations is known as the ionization constant (or as the ionic product) of water, \( K_w \), with a value of 10−14 mol2 dm−6 (at 25 °C). This is a constant in aqueous solutions, so if we know the hydronium ion concentration (which we can get by measuring the pH), we also know the hydroxide concentration since the product of the two concentrations always equals 10−14.

So, roughly at what pH does water become mostly H3O+ ions and at what pH mostly hydroxide ions? We can now add two additional pieces of information to the approximate chart we gave you before. At pH 7, water is almost entirely H2O. At about pH 0, the concentrations of water and H3O+ ions are about the same and at about pH 14, the concentrations of hydroxide ions and water are about the same.

Acids as preservatives

Acetic acid is used as a preservative in many foods, for example pickles, mayonnaise, bread, and fish products, because it prevents bacteria and fungi growing. However, its fungicidal nature is not due to any lowering of the pH of the foodstuff. In fact, it is the undissociated acid that acts as a bactericide and a fungicide in concentrations as low as 0.1–0.3%. Besides, such a low concentration has little effect on the pH of the foodstuff anyway.

Although acetic acid can be added directly to a foodstuff (disguised as E260), it is more common to add vinegar, which contains between 10 and 15% acetic acid. This makes the product more ‘natural’ since it avoids the nasty ‘E numbers’. Actually, vinegar has also replaced other acids used as preservatives, such as propionic (propanoic) acid (E280) and its salts (E281, E282, and E283).

The definition of \( pK_a \)

When we introduced you to \( pK_a \) on p. 167, we said it is the pH at which an acid and its conjugate base are present in equal concentrations. We can now be more precise about the definition...
of pKₐ. pKₐ is the log (to the base ten) of the equilibrium constant for the dissociation of the acid. For an acid HA this is:

$$\text{HA} + \text{H}_2\text{O} \xrightleftharpoons{K_a} \text{H}_3\text{O}^+ + \text{A}^-$$

$$\text{pK}_a = -\log K_a$$

$$K_a = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{AH}]}$$

The concentration of water is ignored in the definition because it is also constant (at 25 °C). Because of the minus sign in the definition (it’s there too in the definition of pH) the lower the pKₐ the larger the equilibrium constant and the stronger the acid. You may find the way we introduced pKₐ more helpful as a concept for visualizing pKₐ: any acid is half dissociated in a solution whose pH matches the acid’s pKₐ. At a pH above the pKₐ the acid exists largely as its conjugate base (A⁻) but at a pH below the pKₐ the acid largely exists as HA.

With pKₐ we can put figures to the relative strengths of hydrochloric and acetic acid we introduced earlier. HCl is a much stronger acid than acetic acid: the pKₐ of HCl is around –7 compared to 4.76 for acetic acid. This tells us that in solution Kₐ for hydrogen chloride is 10⁻⁷ mol dm⁻³. This is an enormous number: only one molecule in 10,000,000 is not dissociated, so it is essentially fully dissociated. But Kₐ for acetic acid is only 10⁻³.⁷⁶ = 1.74 × 10⁻⁵ mol dm⁻³ so it is hardly dissociated at all: only a few molecules in every million of acetic acid are present as the acetate ion.

What about the pKₐ of water? You know the figures already: Kₐ for water is [H₃O⁺] × [HO⁻]/[H₂O] = 10⁻¹⁴/55.5. So pKₐ = −log[10⁻¹⁴/55.5] = 15.7. Now you see why water isn’t really quite half dissociated at pH 14—the concentration of water in the equation means that the two ends of the scale on p. 168 are not at 0 and 14, but at −1.7 and 15.7.

A graphical description of the pKₐ of acids and bases

For both cases, adjusting the pH alters the proportions of the acid form and of the conjugate base. The graph plots the concentration of the free acid AH (green curve) and the ionized conjugate base A⁻ (red curve) as percentages of the total concentration as the pH is varied. At low pH the compound exists entirely as AH and at high pH entirely as A⁻. At the pKₐ the concentration of each species, AH and A⁻, is the same. At pHs near the pKₐ the compound exists as a mixture of the two forms.

Now we have established why you need to understand acids and bases, we must move on to consider why some acids are stronger than other acids and some bases stronger than other bases. To do this we must be able to estimate the pKₐ of common classes of organic compounds.
You do not need to learn exact figures for $pK_a$ values, but you will certainly need to develop a feel for approximate values—we will guide you towards which figures are worth learning and which you can leave to be looked up when you need them.

**An acid's $pK_a$ depends on the stability of its conjugate base**

The stronger the acid, the easier it is to ionize, which means that it must have a stable conjugate base. Conversely, a weak acid is reluctant to ionize because it has an unstable conjugate base. The other side of this coin is that unstable anions $A^-$ make strong bases and their conjugate acids $AH$ are weak acids.

### Acid and conjugate base strength

- The stronger the acid $HA$, the weaker its conjugate base $A^-$.  
- The stronger the base $A^-$, the weaker its conjugate acid $AH$.

For example, hydrogen iodide has a very low $pK_a$, about $\approx 10$. This means that HI is a strong enough acid to protonate almost anything. Its conjugate base, iodide ion, is therefore not basic at all—it will not deprotonate anything. A very powerful base is methylthionium, MeLi. Although it is actually a covalent compound, as we discuss in Chapter 9, for the purpose of the discussion here you can think of MeLi as $\text{CH}_3\text{Li}^-$. $\text{CH}_3^-$ can accept a proton to become neutral methane, $\text{CH}_4$. Methane is therefore the conjugate acid. Clearly, methane isn’t at all acidic—its $pK_a$ is estimated to be 48. The table below gives a few inorganic compounds and their approximate $pK_a$ values.

Notice that the lower down the periodic table we go, the stronger the acid. Notice also that oxygen acids are stronger than nitrogen acids. We have also put down more exact $pK_a$ values for water but you need remember only the approximate values of 0 and 14. Over the next few pages we shall be considering the reasons for these differences in acid strength but we are first going to consider the simple consequences of mixing acids or bases of different strengths. Notice the vast range covered by $pK_a$ values: from around $\approx 10$ for HI to nearly 50 for methane. This corresponds to a difference of $10^{60}$ in the equilibrium constant.

**The choice of solvent limits the $pK_a$ range we can use**

In water, we can measure the $pK_a$ of an acid only if the acid does not completely protonate water to give $\text{H}_3\text{O}^+$ or completely deprotonate it to give $\text{HO}^-$. We are restricted roughly to pH $\approx 1.7$ to 15.7, beyond which water is more than 50% protonated or deprotonated. The strength of acids or bases we can use in any solvent is limited by the acidity and basicity of the solvent itself. Think of it this way: say you want to remove the proton from a compound with a high $pK_a$, say 25–30. It would be impossible to do this in water since the strongest base we can have is hydroxide. If you add a base stronger than hydroxide, it won't deprotonate your compound, it will just deprotonate water and make hydroxide anyway. Likewise, acids stronger than $\text{H}_2\text{O}^+$ can't exist in water: they just protonate water completely to make $\text{H}_3\text{O}^+$. If you do need a stronger base than $\text{OH}^-$ (or a stronger acid than $\text{H}_2\text{O}^+$, but this is rarer) you must use a different solvent.

Let's take acetylene as an example. Acetylene (ethyne) has $pK_a$ 25. This is remarkably low for a hydrocarbon (see below for why) but, even so, hydroxide (the strongest base we could have in aqueous solution, $pK_a$ 15.7) would establish an equilibrium where only 1 in $10^{9.3}$ ($10^{15.7}/10^{25}$), or about 1 in 2 billion, ethyne molecules are deprotonated. We can’t use a stronger base than hydroxide, since, no matter what strong base we dissolve in water, we will only at best get hydroxide ions. So, in order to deprotonate ethyne to any appreciable extent, we must use a different solvent—one that does not have a $pK_a$ less than 25.
Conditions often used to do this reaction are sodium amide (NaNH$_2$) in liquid ammonia. Using the pK$_a$ values of NH$_3$ (ca. 33) and ethyne (25) we would estimate an equilibrium constant for this reaction of $10^{18}$ ($10^{-25}/10^{-33}$)—well over to the right. Amide ions can be used to deprotonate alkynes.

Since we have an upper and a lower limit on the strength of an acid or base that we can use in water, this poses a bit of a problem: how do we know that the pK$_a$ for HCl is more negative than that of H$_2$SO$_4$ if both completely protonate water? How do we know that the pK$_a$ of methane is greater than that of ethyne since both the conjugate bases fully deprotonate water? The answer is that we can’t simply measure the equilibrium for the reaction in water—we can do this only for pK$_a$ values that fall between the pK$_a$ values of water itself. Outside this range, pK$_a$ values are determined in other solvents and the results are extrapolated to give a value for what the pK$_a$ in water might be.

### Constructing a pK$_a$ scale

We now want to look at ways to rationalize, and estimate, the different pK$_a$ values for different compounds—we wouldn’t want to have to memorize all the values. You will need to get a feel for the pK$_a$ values of different compounds and if you know what factors affect them it will make it much easier to predict an approximate pK$_a$ value, or at least understand why a given compound has the pK$_a$ value that it does.

$$\text{AH (solvent)} \rightleftharpoons \text{A}^- \text{ (solvent)} + \text{H}^+ \text{ (solvent)}$$

A number of factors affect the strength of an acid AH. These include:

1. The intrinsic stability of the conjugate base, anion A$^-$. Stability can arise by having the negative charge on an electronegative atom or by spreading the charge over several atoms (delocalization) groups. Either way, the more stable the conjugate base, the stronger the acid HA.
2. Bond strength A–H. Clearly, the easier it is to break this bond, the stronger the acid.
3. The solvent. The better the solvent is at stabilizing the ions formed, the easier it is for the reaction to occur.

#### Acid strength

The most important factor in the strength of an acid is the stability of the conjugate base—the more stable the conjugate base, the stronger the acid.

An important factor in the stability of the conjugate base is which element the negative charge is on—the more electronegative the element, the more stable the conjugate base.

### The negative charge on an electronegative element stabilizes the conjugate base

The pK$_a$ values for the ‘hydrides’ of the first row elements CH$_4$, NH$_3$, H$_2$O, and HF are about 48, 33, 16, and 3, respectively. This trend is due to the increasing electronegativities across the period: F$^-$ is much more stable than CH$_3$$^-$, because fluorine is much more electronegative than carbon.

Weak A–H bonds make stronger acids

However, on descending group VII (group 17), the \( pK_a \) values for HF, HCl, HBr, and HI decrease: 3, –7, –9, and –10. Since the electronegativities decrease on descending the group we might expect an increase in \( pK_a \). The decrease is due to the weakening bond strengths on descending the group and to some extent the way in which the charge can be spread over the increasingly large anions.

Delocalization of the negative charge stabilizes the conjugate base

The acids HClO, HClO\(_2\), HClO\(_3\), and HClO\(_4\) have \( pK_a \) values 7.5, 2, –1, and about –10, respectively. In each case the acidic proton is on an oxygen attached to chlorine, that is, we are removing a proton from the same environment in each case. Why then is perchloric acid, HClO\(_4\), some 17 orders of magnitude stronger in acidity than hypochlorous acid, HClO? Once the proton is removed, we end up with a negative charge on oxygen. For hypochlorous acid, this is localized on the one oxygen. With each successive oxygen, the charge can be more delocalized, and this makes the anion more stable. For example, with perchloric acid, the negative charge can be delocalized over all four oxygen atoms.

</tbody>
</table>

That the charge is spread out over all the oxygen atoms equally is shown by electron diffraction studies: whereas perchloric acid has two types of Cl–O bond, one 163.5 pm and the other three 140.8 pm long, in the perchlorate anion all Cl–O bond lengths are the same, 144 pm, and all O–Cl–O bond angles are 109.5°. Just to remind you: these delocalization arrows do not indicate that the charge is actually moving from atom to atom. We discussed this in Chapter 7. These structures simply show that the charge is spread out in the molecular orbitals and mainly concentrated on the oxygen atoms.

Looking at some organic acids, we might expect alcohols to have a \( pK_a \) not far from that of water, and for ethanol that is correct (\( pK_a 15.9 \)). If we allow the charge in the conjugate base to be delocalized over two oxygen atoms, as in acetate, acetic acid is indeed a much stronger acid (\( pK_a 4.8 \)). The difference is huge: the conjugation makes acetic acid about \( 10^{10} \) times stronger.

charge localized on one oxygen

charge delocalized over two oxygens
It is even possible to have a negative charge of an organic acid delocalized over three atoms—as in the anions of the sulfonic acids. Methanesulfonic acid has a $pK_a$ of –1.9.

Even delocalization into a hydrocarbon part of the molecule increases acid strength. In phenol, $\text{PhOH}$, the $\text{OH}$ group is directly attached to a benzene ring. On deprotonation, the negative charge can again be delocalized, not onto other oxygen atoms but into the aromatic ring itself. The effect of this is to stabilize the phenoxide anion relative to the conjugate base of cyclohexanol, where no delocalization is possible, and this is reflected in the $pK_a$ values of the two compounds: 10 for phenol but 16 for cyclohexanol.

So now we can expand our chart of acid and base strengths to include the important classes of alcohols, phenols, and carboxylic acids. They conveniently, and memorably, have $pK_a$ values of about 0 for the protonation of alcohols, about 5 for the deprotonation of carboxylic acids, about 10 for the deprotonation of phenols, and about 15 for the deprotonation of alcohols. The equilibria above each $pK_a$ shows that at approximately that pH, the two species each form 50% of the mixture. You can see that carboxylic acids are weak acids, alkoxide ions ($\text{RO}^-$) are strong bases, and that it will need a strong acid to protonate an alcohol.

If we need to make the anion of a phenol, a base such as NaOH will be good enough, but if we want to make an anion from an alcohol, we need a stronger base. Vogel (p. 986) suggests potassium carbonate ($\text{K}_2\text{CO}_3$) is strong enough to make an ether from phenol. The base strength of carbonate anion is about the same as that of phenoxide ion ($\text{PhO}^-$) so the two will be in equilibrium but enough phenoxide ion will be present for the reaction.

On the other hand, if we want to make the OH group into a good leaving group, we need to protonate it and a very strong acid will be needed. Sulfuric acid is used to make ethers from alcohols. Protonation of the OH groups leads to loss of water and formation of a cation. This reacts with more alcohol to give the ether. There is another example of this reaction in Chapter 5.
Nitrogen compounds as acids and bases

The most important organic nitrogen compounds are amines and amides. Amine nitrogens can be joined to alkyl or aryl groups (in which case the amines are called anilines). They all have lone pairs on nitrogen and may have hydrogen atoms on nitrogen too. As nitrogen is less electronegative than oxygen, you should expect amines to be less acidic and more basic than alcohols. And they are. The pKₐ values for the protonated amines are about 10 (this value is about 0 for water and alcohol) and the pKₐ values for amines acting as acids are very high, something like 35 (compared with about 15 for an alcohol). So ammonium salts are about as acidic as phenols and amines will be protonated at pH 7 in water. This is why amino acids (p. 167) exist as zwitterions in water.

Removing a proton from an amine is very difficult as the anion (unfortunately called an ‘amide’ anion) is very unstable and very basic. The only way to succeed is to use a very strong base, usually an alkyl lithium. The ‘anion’ then has a N–Li bond and is soluble in organic solvents. This example, known as LDA, is commonly used as a strong base in organic chemistry.

The basicity of amines as neutral compounds is measured by the pKₐ of their conjugate acids—so, for example, the pKₐ associated with the protonation of triethylamine, a commonly used tertiary amine, is 11.0.

The ‘pKₐs’ of bases

Chemists often say things like ‘the pKₐ of triethylamine is about 10.’ (It’s actually 11.0 but 10 is a good number to remember for typical amines). This may surprise you as triethylamine has no acidic hydrogens. What they mean is of course this: ‘the pKₐ of the conjugate acid of triethylamine is about 10.’ Another way to put this is to write ‘the pKₐ of triethylamine is about 10.’ The subscript ‘aH’ refers to the conjugate acid.

It’s OK to say ‘the pKₐ of triethylamine is about 10’ as long as you understand that what is really meant is ‘the pKₐ of the triethylammonium ion is about 10’, which can also be expressed thus: ‘the pKₐ of triethylamine is about 10’

When a molecule is both acidic and basic, as for example aniline, it is important to work out which pKₐ is meant as again chemists will loosely refer to ‘the pKₐ of aniline is 4.6’ when they mean ‘the pKₐ of the conjugate acid of aniline is 4.6.’ Aniline is much less basic than ammonia or triethylamine because the lone pair on nitrogen is conjugated into the ring and less available for protonation.
But for the same reason, aniline is also more acidic than ammonia ($pK_a 33$) and has a genuine $pK_a$ in which one of the protons on nitrogen is lost. So we can say correctly that ‘the $pK_a$ of aniline is about 28.’ Just be careful to check which $pK_a$ is meant in such compounds. The full picture is:

$$\text{NH}_2 \xrightarrow{\text{ conjugate acid of aniline } } \text{ aniline} \xrightarrow{\text{ conjugate base of aniline } } \text{ delocalized anion is more stable}$$

The $pK_a$ associated for protonation of piperidine, a typical secondary amine, is about 13. The equivalent $pK_a$ for protonation of pyridine—a compound with a similar heterocyclic structure, but with its lone pair in an $sp^2$ rather than an $sp^3$ orbital, is only 5.5: pyridine is a weaker base than piperidine (its conjugate acid is a stronger acid). Nitriles, whose lone pair is $sp$ hybridized, are not basic at all. Lone pairs with more $p$ character ($sp^3$ orbitals are $3/4$ $p$, while $sp$ orbitals are $1/2$ $p$) are higher in energy—they spend more time further from the nucleus—and are therefore more basic.

Amides are very different because of the delocalization of the lone pair into the carbonyl group. This makes amides more acidic but less basic and protonation occurs on oxygen rather than nitrogen. Amides have $pK_a$ values of around 15 when they act as acids, making them some $10^{10}$ times more acidic than amines. The $pK_a$ of protonated amides is around 0, making them some $10^{10}$ times weaker as bases.

If we replace the carbonyl oxygen atom in an amide by nitrogen we get an amidine. Amidines are conjugated, like amides, but unlike amides they are stronger bases than amines, by about 2–3 $pK_a$ units, because the two nitrogens work together to donate electron density onto each other. The bicyclic amidine DBU is often used as a strong organic base (see Chapter 17).

But the champions are the guanidines, with three nitrogens all donating lone pair electrons at once. A guanidine group (shown in green) makes arginine the most basic of the amino acids.

**Substituents affect the $pK_a$**

Substituents that are conjugated with the site of proton gain or loss, and even substituents that are electronegative but not conjugating, can have significant effects on $pK_a$ values. Phenol has $pK_a 10$ but phenols with anions stabilized by extra conjugation can have much lower $pK_a$s.
One nitro group, as in p-nitrophenol, lowers the pKₐ to 7.14, nearly a thousand-fold increase in acidity. This is because the negative charge on oxygen is delocalized into the very electron-withdrawing nitro group. By contrast 4-chlorophenol, with only inductive withdrawal in the C–Cl bond, has pKₐ 9.38, hardly different from phenol itself.

Inductive effects of nearby electronegative atoms can also have marked effects on the pKₐ of acids. Adding fluorines to acetic acid reduces the pKₐ from about 5 by smallish steps. Trifluoroacetic acid (TFA) is a very strong acid indeed, and is commonly used as a convenient strong acid in organic reactions. Inductive effects occur by polarization of σ bonds when the atom at one end is more electronegative than at the other. Fluorine is much more electronegative than carbon (indeed, F is the most electronegative element of all) so each σ bond is very polarized, making the carbon atom more electropositive and stabilizing the carboxylate anion.

**Carbon acids**

Hydrocarbons are not acidic. We have already established that methane has a pKₐ of about 48 (p. 170 above)—it’s essentially impossible to deprotonate. Alkyllithiums are for this reason among the strongest bases available. But some hydrocarbons can be deprotonated, the most important example being alkynes—you saw on p. 171 that acetylene has a pKₐ of 25 and can be deprotonated by NH₂⁻ (as well as other strong bases such as BuLi). The difference is one of hybridization—an idea we introduced with the nitrogen bases above. Making the acetylide anion, whose negative charge resides in an sp orbital, is much easier than making a methyl anion, with a negative charge in an sp³ orbital, because electrons in sp orbitals spend a lot of their time closer to the nucleus than electrons in sp³ orbitals.

C–H bonds can be even more acidic than those of acetylene if stabilization of the resulting anion is possible by *conjugation*. Conjugation with a carbonyl group has a striking effect. One carbonyl group brings the pKₐ down to 13.5 for acetaldehyde so that even hydroxide ion can produce the anion. You will discover in Chapter 20 that we call this the ‘enolate anion’ and that the charge is mostly on oxygen, although the anion can be drawn as a carbanion.

It is interesting to compare the strengths of the carbon, nitrogen, and oxygen acids of similar structure below. The ketone (acetone) is of course least acidic, the amide is more acidic, and the carboxylic acid most acidic. The oxyanion conjugate bases are all delocalized but delocalization onto a second very electronegative oxygen atom is much (~10 pH units) more effective than delocalization onto nitrogen, which is 4 pH units more effective than delocalization onto carbon.
Nevertheless, the effect of conjugation on the carbon acid compared with methane is enormous (~30 pH units) and brings proton removal from carbon within the range of accessible bases.

The nitro group is even more effective: nitromethane, with a $pK_a$ of 10, dissolves in aqueous NaOH. The proton is removed from carbon, but the negative charge in the conjugate base is on oxygen. The big difference is that the nitrogen atom has a positive charge throughout. If the anion is protonated in water by some acid (HA) the ‘enol’ form of nitromethane is the initial product and this slowly turns into nitromethane itself. Whereas proton transfers between electronegative atoms (O, N, etc.) are fast, proton transfers to or from carbon can be slow.

[Chemical structure diagram]

Carbon acids are very important in organic chemistry as they allow us to make carbon–carbon bonds and you will meet many more of them in later chapters of this book.

**Why do we need to compare acid strengths of O and N acids?**

The rates of nucleophilic addition to carbonyl groups that you met in Chapter 6 depend on the basicity of nucleophiles. As nitrogen bases are much stronger than oxygen bases (or, if you prefer, ammonium ions are much weaker acids than $H_3O^+$), amines are also much better nucleophiles than water or alcohols. This is dramatically illustrated in an amide synthesis from aniline and acetic anhydride in aqueous solution.

[Chemical structure diagram]

Aniline is not very soluble in water but addition of HCl converts it into the soluble cation by protonation at nitrogen. The solution is now warmed and equal amounts of acetic anhydride and aqueous sodium acetate are added. The $pK_a$ of acetic acid is about 5, as is the $pK_a$ of $PhNH_3^+$, so an equilibrium is set up and the solution now contains these species:

[Chemical structure diagram]

The only electrophile is acetic anhydride, with its two electrophilic carbonyl groups. The nucleophiles available are water, aniline, and acetate. Water is there in great abundance and does react with acetic anhydride but can’t compete with the other two as they are more basic (by about $10^5$). If acetate attacks the anhydride, it simply regenerates acetate. But if aniline attacks, the amide is formed as acetate is released.

[Chemical structure diagram]

The isolation of the product is easy as the amide is insoluble in water and can be filtered off. Environmental considerations suggest that we should not use organic solvents so much and should use water when possible. If we have some idea about $pK_a$s we can estimate whether water will interfere in a reaction we are planning and decide whether it is a suitable solvent or not. It is even possible to acylate amines with the more reactive acid chlorides in aqueous solution, and we will return in detail to acylation reactions such as these in Chapter 10.
**pKₐ in action—the development of the drug cimetidine**

The development of the anti-peptic ulcer drug cimetidine gives a fascinating insight into the important role of pKₐ in chemistry. Peptic ulcers are a localized erosion of the mucous membrane, resulting from overproduction of gastric acid in the stomach. One of the compounds that controls the production of the acid is histamine. (Histamine is also responsible for the symptoms of hay fever and allergies.)

![Cimetidine and Histamine](image)

Histamine works by binding into a receptor in the stomach lining and stimulating the production of acid. What the developers of cimetidine at Smith, Kline and French wanted was a drug that would bind to these receptors without activating them and thereby prevent histamine from binding but not stimulate acid secretion itself. Unfortunately, the antihistamine drugs successfully used in the treatment of hay fever did not work—a different histamine receptor was involved.

Notice that cimetidine and histamine both have the same nitrogen-containing ring (shown in black) as part of their structures. This ring is known as an imidazole—imidazole itself is quite a strong base whose protonated form is delocalized as shown below. This is not coincidence—cimetidine’s design was centred around the structure of histamine.

![Imidazole and Delocalization](image)

In the body, most histamine exists as a salt, being protonated on the primary amine and the early compounds modelled this. The guanidine analogue was synthesized and tested to see if it had any antagonistic effect (that is, if it could bind in the histamine receptors and prevent histamine binding). It did bind but unfortunately it acted as an agonist rather than an antagonist and stimulated acid secretion rather than blocking it. Since the guanidine analogue has a pKₐ even greater than histamine (about 14.5 compared to about 10), it is effectively all protonated at physiological pH.

![pKₐ Values](image)

The agonistic behaviour of the drug clearly had to be suppressed. The thought occurred to the chemists that perhaps the positive charge made the compound agonistic, and so a polar but much less basic compound was sought. Eventually, they came up with burimamide. The most important change is the replacement of the C=NH in the guanidine compound by C=S. Now instead of a guanidine we have a thiourea, which is much less basic. Other adjustments were to increase the chain length, insert a second sulfur atom on the chain, and add methyl groups to the thiourea and the imidazole ring, to give metiamide with increased efficacy.
The new drug, metiamide, was ten times more effective than burimamide when tested in humans. However, there was an unfortunate side-effect: in some patients, the drug caused a decrease in the number of white blood cells, leaving the patient open to infection. This was eventually traced back to the thiourea group. The sulfur had again to be replaced by oxygen, to give a normal urea and, just to see what would happen, by nitrogen to give another guanidine.

Neither was as effective as metiamide but the important discovery was that the guanidine analogue no longer showed the agonistic effects of the earlier guanidine. Of course, the guanidine would also be protonated so we had the same problem we had earlier—how to decrease the pKₐ of the guanidinium ion. A section of this chapter considered the effect of electron-withdrawing groups on pKₐ and showed that they make a base less basic. This was the approach now adopted—the introduction of electron-withdrawing groups on to the guanidine to lower its pKₐ. The table below shows the pKₐs of various substituted guanidinium ions.

Clearly, the cyano and nitro-substituted guanidines would not be protonated at all. These were synthesized and found to be just as effective as metiamide but without the side-effects. Of the two, the cyanoguanidine compound was slightly more effective and this was developed and named ‘cimetidine’.
The development of cimetidine by Smith, Kline and French from the very start of the project up to its launch on the market took 13 years. This enormous effort was well rewarded—Tagamet (the trade name of the drug cimetidine) became the best-selling drug in the world and the first to gross more than one billion dollars per annum. Thousands of ulcer patients worldwide no longer had to suffer pain, surgery, or even death. The development of cimetidine followed a rational approach based on physiological and chemical principles and it was for this that one of the scientists involved, Sir James Black, received a share of the 1988 Nobel Prize for Physiology or Medicine. None of this would have been possible without an understanding of $pK_a$.

### Lewis acids and bases

All the acids and bases we have been discussing so far have been protic, or Brønsted, acids and bases. In fact, the definition of an acid and a base we gave you on p. 165 is a definition of a Brønsted acid and a Brønsted base. When a carboxylic acid gives a proton to an amine, it is acting as a Brønsted acid while the amine is a Brønsted base. The ammonium ion produced is a Brønsted acid while the carboxylate anion is a Brønsted base.

- Brønsted acids donate protons.
- Brønsted bases accept protons.

But there is another important type of acid: the Lewis acid. These acids don’t donate protons—indeed they usually have no protons to donate. Instead they accept electrons. It is indeed a more general definition of acids to say that they accept electrons and of bases that they donate electrons. Lewis acids are usually halides of the higher oxidation states of metals, such as $\text{BF}_3$, $\text{AlCl}_3$, $\text{ZnCl}_2$, $\text{SbF}_5$, and $\text{TiCl}_4$. By removing electrons from organic compounds, Lewis acids act as important catalysts in important reactions such as the Friedel–Crafts alkylation and acylation of benzene (Chapter 21), the $S_{N1}$ substitution reaction (Chapter 15), and the Diels–Alder reaction (Chapter 34).

- Lewis acids accept electrons.
- Lewis bases donate electrons.

A simple Lewis acid is $\text{BF}_3$. As you saw in Chapter 5, monomeric boron compounds have three bonds to other atoms and an empty p orbital, making six electrons only in the outer shell. They are therefore not stable and $\text{BF}_3$ is normally used as its ‘etherate’: a complex with $\text{Et}_2\text{O}$. Ether donates a pair of electrons into the empty p orbital of $\text{BF}_3$ and this complex has tetrahedral boron with eight electrons. In this reaction the ether donates electrons (it can be described as a Lewis base) and $\text{BF}_3$ accepts electrons: it is a Lewis acid. No protons are exchanged. The complex is a stable liquid and is the form usually available from suppliers.

Lewis acids often form strong interactions with electronegative atoms such as halides or oxygen. In the Friedel–Crafts acylation, which you will meet in Chapter 21, for example, $\text{AlCl}_3$ removes the chloride ion from an acyl chloride to give a species, the acylium ion, which is reactive enough to combine with benzene.
Lewis acid–base interactions are very common in chemistry and are often rather subtle. You are about to meet, in the next chapter, an important way of making C–C bonds by adding organometallics to carbonyl compounds, and in many of these reactions there is an interaction at some point between a Lewis acidic metal cation and a Lewis basic carbonyl group.

Introduction

In Chapters 2–8 we covered basic chemical concepts concerning structure (Chapters 2–4 and 7) and reactivity (Chapters 5, 6, and 8). These concepts are the bare bones supporting all of organic chemistry, and now we shall start to put flesh on these bare bones. In Chapters 9–22 we shall tell you about the most important classes of organic reaction in more detail.

One of the things organic chemists do, for all sorts of reasons, is to make molecules, and making organic molecules means making C–C bonds. In this chapter we are going to look at one of the most important ways of making C–C bonds: using organometallics, such as organolithiums and Grignard reagents, in combination with carbonyl compounds. We will consider reactions such as these:

You met these types of reactions in Chapter 6: in this chapter we will be adding more detail with regard to the nature of the organometallic reagents and what sort of molecules can be made using the reactions. The organometallic reagents act as nucleophiles towards the

Online support. The icon in the margin indicates that accompanying interactive resources are provided online to help your understanding: just type www.chemtube3d.com/clayden/123 into your browser, replacing 123 with the number of the page where you see the icon. For pages linking to more than one resource, type 123-1, 123-2 etc. (replacing 123 with the page number) for access to successive links.
electrophilic carbonyl group, and this is the first thing we need to discuss: why are organometallics nucleophilic? We then move on to, firstly, how to make organometallics, then to the sorts of electrophiles they will react with, and finally to the sort of molecules we can make with them.

**Organometallic compounds contain a carbon—metal bond**

The polarity of a covalent bond between two different elements is determined by electronegativity. The more electronegative an element is, the more it attracts the electron density in the bond. So the greater the difference between the electronegativities, the greater the difference between the attraction for the bonding electrons, and the more polarized the bond becomes. In the extreme case of complete polarization, the covalent bond ceases to exist and is replaced by electrostatic attraction between ions of opposite charge. We discussed this in Chapter 4 (p. 96), where we considered the extreme cases of bonding in NaCl.

**How important are organometallics for making C–C bonds?**

As an example, let’s take a molecule known as ‘juvenile hormone’. It is a compound that prevents several species of insects from maturing and can be used as a means of controlling insect pests. Only very small amounts of the naturally occurring compound can be isolated from the insects, but it can instead be made in the laboratory from simple starting materials. At this stage you need not worry about how, but we can tell you that, in one synthesis, of the 16 C–C bonds in the final product, seven were made by reactions of organometallic reagents, many of them the sort of reactions we will describe in this chapter. This is not an isolated example. As further proof, take an important enzyme inhibitor, closely related to arachidonic acid which you met in Chapter 7. It has been made by a succession of C–C bond-forming reactions using organometallic reagents: eight of the 20 C–C bonds in the product were formed using organometallic reactions.

When we discussed (in Chapter 6) the electrophilic nature of carbonyl groups we saw that their reactivity is a direct consequence of the polarization of the carbon—oxygen bond towards the more electronegative oxygen, making the carbon a site for nucleophilic attack. In Chapter 6 you also met the two most important organometallic compounds—organolithiums and organomagnesium halides (known as Grignard reagents). In these organometallic reagents the key bond is polarized in the opposite direction—towards carbon—making carbon a nucleophilic centre. This is true for most organometallics because, as you can see from this edited version of the periodic table, metals (such as Li, Mg, Na, and Al) all have lower electronegativity than carbon.

The molecular orbital energy level diagram—the kind you met in Chapter 4—represents the C–Li bond in methyllithium in terms of the sum of the atomic orbitals of carbon and lithium. The more electronegative an atom is, the lower in energy are its atomic orbitals (p. 96). The filled C–Li σ orbital is closer in energy to the carbon’s sp³ orbital than to the lithium’s 2s orbital, so we can say that the carbon’s sp³ orbital makes a greater contribution to the C–Li σ bond and that the C–Li bond has a larger coefficient on carbon. Reactions involving the filled
σ orbital will therefore take place at C rather than Li. The same arguments hold for the C–Mg bond of organo-magnesium or Grignard reagents, named after their inventor Victor Grignard.

We can also say that, because the carbon’s sp³ orbital makes a greater contribution to the C–Li σ bond, the σ bond is close in structure to a filled C sp³ orbital—a lone pair on carbon. This useful idea can be carried too far: methyl lithium is not an ionic compound Me⁻Li⁺—although you may sometimes see MeLi or MeMgCl represented in mechanisms as Me⁻.

The true structure of organolithiums and Grignard reagents is rather more complicated! Even though these organometallic compounds are extremely reactive towards water and oxygen, and have to be handled under an atmosphere of nitrogen or argon, some have been studied by X-ray crystallography in the solid state and by NMR in solution. It turns out that they generally form complex aggregates with two, four, six, or more molecules bonded together, often with solvent molecules, one reason why apparently polar compounds such as BuLi dissolve in hydrocarbons. In this book we shall not be concerned with these details, and we shall represent organometallic compounds as simple monomeric structures.

Making organometallics

How to make Grignard reagents

Grignard reagents are made by reacting magnesium turnings with alkyl halides in ether solvents to form solutions of alkylmagnesium halide. Iodides, bromides, and chlorides can be used, as can both aryl and alkyl halides. Our examples include methyl, primary, secondary, and tertiary alkyl halides, aryl and allyl halides. They cannot contain any functional groups that would react with the Grignard reagent once it is formed. The final example has an acetal functional group as an example of one that does not react with the Grignard reagent. (See Chapter 23 for further discussion.)
The solvents in these examples are all ethers, either diethyl ether $\text{Et}_2\text{O}$ or THF. Other solvents that are sometimes used include the diethers dioxane and dimethoxyethane (DME).

The reaction scheme is easy enough to draw, but what is the mechanism? Overall it involves an insertion of magnesium into the carbon–halogen bond. There is also a change in oxidation state of the magnesium, from Mg(0) to Mg(II). The reaction is therefore known as an oxidative insertion or oxidative addition, and is a general process for many metals such as Mg, Li (which we meet shortly), Cu, and Zn. Mg(II) is much more stable than Mg(0) and this drives the reaction.

The mechanism of the reaction is not completely understood, and probably involves radical intermediates. But what is sure is that by the end of the reaction the magnesium has surrendered its lone pair of electrons and gained two $\sigma$ bonds. The true product is a complex between the Grignard reagent and, probably, two molecules of the ether solvent, as Mg(II) prefers a tetrahedral structure.

More on making Grignard reagents

The reaction takes place not in solution but on the surface of the metal, and how easy it is to make a Grignard reagent can depend on the state of the surface—how finely divided the metal is, for example. Magnesium is usually covered by a thin coating of magnesium oxide, and Grignard formation generally requires ‘initiation’ to allow the metal to come into direct contact with the alkyl halide. Initiation usually means adding a small amount of iodine or 1,2-diodoethane, or using ultrasound to dislodge the oxide layer. Once the Grignard starts to form, it catalyses further reactions of Mg(0), perhaps by this mechanism:

**How to make organolithium reagents**

Organolithium compounds may be made by a similar oxidative insertion reaction from lithium metal and alkyl halides. Each inserting reaction requires two atoms of lithium and generates one equivalent of lithium halide salt. As with Grignard formation, there is really very little limit on the types of organolithium that can be made this way.

You will notice secondary alkyllithiums, an aryllithium, and two vinyllithiums. The only other functional groups are alkenes and an ether. So far, that is quite like the formation of Grignard reagents. However, there are differences. Lithium goes from Li(0) to Li(I) during the
reaction and there is no halide attached to the Li. Instead a second Li atom has to be used to make the Li halide. Again, Li(I) is very much more stable than Li(0) so the reaction is irreversible. Although ether solvents are often used, there is less need for extra coordination and hydrocarbon solvents such as pentane or hexane are also good.

Commercially available organometallics

Some Grignard and organolithium reagents are commercially available. Most chemists (unless they were working on a very large scale) would not usually make the simpler organolithiums or Grignard reagents by these methods, but would buy them in bottles from chemical companies (who, of course, do use these methods). The table lists some of the most important commercially available organolithiums and Grignard reagents.

Organometallics as bases

Organometallics need to be kept absolutely free of moisture—even moisture in the air will destroy them. The reason is that they react very rapidly and highly exothermically with water to produce alkanes. Anything that can protonate them will do the same thing. The organometallic reagent is a strong base, and is protonated to form its conjugate acid—methane or benzene in these cases. The pKₐ of methane (Chapter 8) is somewhere around 50: it isn’t an acid at all and essentially nothing will remove a proton from methane.

The equilibria lie vastly to the right: methane and Li⁺ are much more stable than MeLi while benzene and Mg²⁺ are much more stable than PhMgBr. Some of the most important uses of organolithiums—n-butyllithium, in particular—are as bases and, because they are so strong, they will deprotonate almost anything. That makes them very useful as reagents for making other organolithiums.

Making organometallics by deprotonating alkynes

In Chapter 8 (p. 175) we talked about how hybridization affects acidity. Alkynes, with their C–H bonds formed from sp orbitals, are the most acidic of hydrocarbons, with pKₐ's of about 25.
They can be deprotonated by more basic organometallics such as butyllithium or ethylmagne- 
sium bromide. Alkynes are sufficiently acidic to be deprotonated even by nitrogen bases and 
you saw on p. 171 that a common way of deprotonating alkynes is to use NaNH₂ (sodium 
amide), obtained by reacting sodium with liquid ammonia. An example of each is shown here. 
Propyne and acetylene are gases, and can be bubbled through a solution of the base.

The metal derivatives of alkynes can be added to carbonyl electrophiles, as in the following 
examples. The first (we have reminded you of the mechanism for this) is the initial step of an 
important synthesis of the antibiotic erythronolide A, and the second is the penultimate step 
of a synthesis of the widespread natural product farnesol.

**Ethynyloestradiol**
The ovulation-inhibiting component of almost all oral contraceptive pills is a compound known as ethynyloestradiol, and this compound too is made by an alkynyllithium addition to the female sex hormone oestrone. A range of similar synthetic 
analogues of hormones containing an ethynyl unit are used in contraceptives and in treatments for disorders of the 
hormonal system.
**Triple bonds: stability and acidity**

You have now met all the more important compounds with triple bonds. They all have electrons in low-energy sp hybrid orbitals (shown in green on the diagrams below), a feature which gives them stability or even unreactivity. Remember, an sp orbital has 50% s character, so electrons in this orbital are on average closer to the nucleus, and therefore more stable, than electrons in an sp$^2$ or sp$^3$ orbital.

Nitrogen, N$_2$, has sp orbitals at both ends and is almost inert. It is neither basic nor nucleophilic and a major achievement of life is the ‘fixing’ (trapping in reductive chemical reactions) of nitrogen by bacteria such as those in the roots of leguminous plants (peas and beans). HCN has an sp orbital on nitrogen and a C–H σ bond at the other end. The nitrogen’s sp lone pair is not at all basic, but HCN is quite acidic with a pK$_a$ of 10 because the negative charge in the conjugate base (CN$^-$) is in an sp orbital. Nitriles have similar bonds and they are non-nucleophilic and non-basic. Finally, we have just met alkynes, which are among the most acidic of hydrocarbons, again because of the stability of an anion with its charge in an sp orbital.

![Diagram of nitrogen, HCN, nitrile, and alkyne structures with pK$_a$ values.](image)

**Halogen–metal exchange**

Deprotonation is not the only way to use one simple organometallic reagent to generate another more useful one. Organolithiums can also remove halogen atoms from alkyl and aryl halides in a reaction known as halogen–metal exchange.

![Diagram of bromine and lithium swap places in halogen–metal exchange.](image)

The bromine and the lithium simply swap places. As with many of these organometallic processes, the mechanism is not altogether clear, but can be represented as a nucleophilic attack on bromine by the butyllithium. But why does the reaction work? The product of our ‘mechanism’ is not PhLi and BuBr but a phenyl anion and a lithium cation. These could obviously combine to give PhLi and BuBr. But is this a reasonable interpretation and why does the reaction go that way and not the other? The key, again, is pK$_a$. We can think of the organolithiums as a complex between Li$^+$ and a carbanion.

![Diagram of organolithium complexes showing polarised σ-bonds.](image)

The lithium cation is the same in all cases: only the carbanion varies. So the stability of the complex depends on the stability of the carbanion ligand. Benzene, (pK$_a$ about 43) is more acidic than butane (pK$_a$ about 50) so the phenyl complex is more stable than the butyl complex and the reaction is a way to make PhLi from available BuLi. Vinyllithiums (the lithium must be bonded directly to the alkene) can also be made this way and a R$_2$N– substituent is acceptable. Bromides or iodides react faster than chlorides.

![Diagram of organolithium reactions with different substituents.](image)
Halogen–metal exchange tolls the knell of one appealing way to make carbon–carbon bonds. It may already have occurred to you that we might make a Grignard or organolithium reagent and combine it with another alkyl halide to make a new carbon–carbon σ bond.

\[
\begin{array}{c}
R^1\text{Br} & \xrightarrow{\text{Et}_2\text{O}} & Mg & \xrightarrow{\text{R}^2\text{Br}} & R^1\text{MgBr} \\
\text{NOT successful}
\end{array}
\]

This reaction does not work because of transmetallation. The two alkyl bromides and their Grignard reagents will be in equilibrium with each other so that, even if the coupling were successful, three coupled products will be formed.

\[
R^1\text{MgBr} + R^2\text{Br} \rightleftharpoons R^1\text{Br} + R^2\text{MgBr}
\]

You will see later that transition metals are needed for this sort of reaction. The only successful reactions of this kind are couplings between metal derivatives of alkynes and alkyl halides. These do not exchange the metal as the alkynyl metal is much more stable than the alkyl metal.

A good example is the synthesis of a substituted alkyne starting from acetylene (ethyne) itself. One alkylation uses NaNH\textsubscript{2} as the base to make sodium acetylide and the other uses BuLi to make a lithium acetylide.

\[
\begin{array}{c}
\text{H--H} & \xrightarrow{\text{NaNH}_2, \text{xylene, DMF}} & \text{H--Na} \\
\text{H--Bu} & \xrightarrow{\text{BuLi}} & \text{Li--Bu} & \xrightarrow{n\text{-C}_3\text{H}_{11}\text{Cl}} & \text{81% yield} \\
\text{81% yield}
\end{array}
\]

Transmetallation

Organolithiums can be converted to other types of organometallic reagents by transmetallation—simply treating with the salt of a less electropositive metal. The more electropositive Mg or Li goes into solution as an ionic salt, while the less electropositive metal such as Zn takes over the alkyl group.

\[
\begin{array}{c}
R\text{MgBr} & \xrightarrow{\text{ZnBr}_2} & Mg\text{Br}_2 + R\text{ZnR} \\
\text{Grignard} & \text{dialkylzinc} & \text{basic zinc hydroxide}
\end{array}
\]

But why bother? Well, the high reactivity—and in particular the basicity—of Grignard reagents and organolithiums sometimes causes unwanted side reactions. Their combination with very strong electrophiles like acid chlorides usually results in a violent uncontrolled reaction. If a much less reactive organozinc compound is used instead, the reaction is more under control. These organozinc compounds can be made from either Grignard reagents or organolithium compounds. E. Negishi, a pioneer of organozinc chemistry, got the Nobel Prize for Chemistry in 2010 with R. F. Heck and A. Suzuki for their work on organometallic compounds.

Using organometallics to make organic molecules

Now that you have met all of the most important ways of making organometallics (summarized here as a reminder), we shall move on to consider how to use them to make molecules:
what sorts of electrophiles do they react with and what sorts of products can we expect to get from their reactions? Having told you how you can make other organometallics, we shall really be concerned for the rest of this chapter only with Grignard reagents and organolithiums. In nearly all of the cases we shall talk about, the two classes of organometallics can be used interchangeably.

[Diagram of Ways of making organometallics]

**Making carboxylic acids from organometallics and carbon dioxide**

Carbon dioxide reacts with organolithiums and Grignard reagents to give carboxylate salts. Protonating the salt with acid gives a carboxylic acid with one more carbon atom than the starting organometallic. The reaction is usually done by adding solid CO2 to a solution of the organolithium in THF or ether, but it can also be done using a stream of dry CO2 gas.

[Diagram of Making carboxylic acids from organometallics and carbon dioxide]

The example below shows the three stages of the reaction: (1) forming the organometallic, (2) reaction with the electrophile (CO₂), and (3) the acidic work-up or quench, which protonates the product and destroys any unreacted organometallic. The three stages of
the reaction have to be monitored carefully to make sure that each is finished before the next is begun. In particular it is absolutely essential that there is no water present during either of the first two stages—water must be added only at the end of the reaction, after the organometallic has all been consumed by reaction with the electrophile. You may occasionally see schemes written out without the quenching step included, but it is nonetheless always needed.

carboxylic acids from organometallics

This next example shows that even very hindered chlorides can be used successfully. The significance of this will be clearer when you reach Chapter 15.

Making primary alcohols from organometallics and formaldehyde

You met formaldehyde, the simplest aldehyde, in Chapter 6, where we discussed the difficulties of using it in anhydrous reactions: it is either hydrated or a polymer paraformaldehyde, \((\text{CH}_2\text{O})_n\), and in order to get pure, dry formaldehyde it is necessary to heat (‘crack’) the polymer to decompose it. But formaldehyde is a remarkably useful reagent for making primary alcohols, in other words alcohols that have just one carbon substituent on the hydroxy-bearing C atom. Just as carbon dioxide adds one carbon and makes an acid, formaldehyde adds one carbon and makes an alcohol.

In the next two examples, formaldehyde makes a primary alcohol from two deprotonated alkynes. The second reaction here (for which we have shown organolithium formation, reaction, and quench simply as a series of three consecutive reagents) forms one of the last steps of the synthesis of *Cecropia* juvenile hormone, whose structure you met right at the beginning of the chapter.
Something to bear in mind with all organometallic additions to carbonyl compounds is that the addition takes the oxidation level down one (oxidation levels were described in Chapter 2, p. 33). In other words, if you start with an aldehyde, you end up with an alcohol. More specifically,

- additions to CO₂ give carboxylic acids
- additions to formaldehyde (CH₂O) give primary alcohols
- additions to other aldehydes (RCHO) give secondary alcohols
- additions to ketones give tertiary alcohols

Secondary and tertiary alcohols: which organometallic, which aldehyde, which ketone?

Aldehydes and ketones react with organometallic reagents to form secondary and tertiary alcohols, respectively, and some examples are shown with the general schemes here.

Fenarimol

Fenarimol is a fungicide that works by inhibiting the fungus’s biosynthesis of important steroid molecules. It is made by reaction of a diarylketone with an organolithium derived by halogen–metal exchange.

To make any secondary alcohol, however, there may be a choice of two possible routes, depending on which part of the molecule you choose to make the organometallic and which part you choose to make the aldehyde. For example, the first example here shows the synthesis of a secondary alcohol from isopropylmagnesium chloride and acetaldehyde. But it is
equally possible to make this same secondary alcohol from isobutyraldehyde and methyl-lithium or a methylmagnesium halide.

Indeed, back in 1912, when this alcohol was first described in detail, the chemists who made it chose to start with acetaldehyde, while in 1983, when it was needed as a starting material for a synthesis, it was made from isobutyraldehyde. Which way is better? The 1983 chemists probably chose the isobutyraldehyde route because it gave a better yield. But, if you were making a secondary alcohol for the first time, you might just have to try both in the laboratory and see which one gave a better yield.

Or you might be more concerned about which uses the cheaper, or more readily available, starting materials—this was probably also a factor in the choice of methylmagnesium chloride and the unsaturated aldehyde in the second example. Both can be bought commercially, while the alternative route to this secondary alcohol would require a vinylolithium or vinylmagnesium bromide reagent that would have to be made from a vinyl halide, which is itself not commercially available, along with difficult-to-dry acetaldehyde.

There is another choice for secondary alcohols: the reduction of a ketone. The ketone reacts with sodium borohydride to give a secondary alcohol. An obvious case where this would be a good route is the synthesis of a cyclic alcohol. This bicyclic ketone gives the secondary alcohol in good yield, and in the second example a diketone has both its carbonyl groups reduced.

Flexibility in the synthesis of alcohols

As an illustration of the flexibility available in making secondary alcohols, one synthesis of bongkreic acid, a highly toxic compound that inhibits transport across certain membranes in the cell, requires both of these (very similar) alcohols. The chemists making the compound at Harvard University chose to make each alcohol from quite different starting materials: an unsaturated aldehyde and an alkyne-containing organolithium in the first instance, and an alkyne-containing aldehyde and vinylmagnesium bromide in the second.

With tertiary alcohols, there is even more choice. The example below is a step in a synthesis of the natural product, nerolidol. But the chemists in Paris who made this tertiary alcohol...
could in principle have chosen any of three routes. Note that we have dropped the aqueous quench step from these schemes to avoid cluttering them.

Only the reagents in orange are commercially available, but, as it happens, the green Grignard reagent can be made from an alkyl bromide, which is itself commercially available, making route 1 on the left the most reasonable.

Now, do not be dismayed! We are not expecting you to remember a chemical catalogue and to know which compounds you can buy and which you can’t. All we want you to appreciate at this stage is that there are usually two or three ways of making any given secondary or tertiary alcohol, and you should be able to suggest alternative combinations of aldehyde or ketone and Grignard or organolithium reagent that will give the same product. You are not expected to be able to assess the relative merits of the different possible routes to a compound. That is a topic we leave for a much later chapter on retrosynthetic analysis, Chapter 28.

**Oxidation of alcohols**

So far the metals we have used have had one oxidation state other than zero: Li(I), Mg(II), and Zn(II). If we want to oxidize organic compounds we need metals that have at least two higher oxidation states and that means transition metals. The most important by far is chromium, with Cr(III) and Cr(VI) as the useful oxidation states. Orange Cr(VI) compounds are good oxidizing agents: they remove hydrogen from organic compounds and are themselves reduced to green Cr(III). There are many Cr(VI) reagents used in organic chemistry, some of the more important ones are related to the polymeric oxide CrO₃. This is the anhydride of chromic acid and water breaks up the polymer to give a solution of chromic acid. Pyridine also breaks up the polymer to give a complex. This (Collins’ reagent) was used to oxidize organic compounds but it is rather unstable and pyridinium dichromate (PDC) and pyridinium chlorochromate (PCC) are usually now preferred, especially as they are soluble in organic solvents such as CH₂Cl₂.

Oxidation by these reagents of the various primary and secondary alcohols we have been making in this chapter takes us to a higher oxidation level. Oxidation of primary alcohols gives aldehydes and then carboxylic acids, while oxidation of secondary alcohols gives ketones. Note that you can’t oxidize tertiary alcohols (without breaking a C–C bond).

The symbol [O] means an unspecified oxidizing agent.
You will notice that the oxidation steps involve the removal of two hydrogen atoms and/or the addition of one oxygen atom. In Chapter 6 you saw that reduction meant the addition of hydrogen (and can also mean the removal of oxygen). Hiding behind these observations is the more fundamental idea that reduction requires the addition of electrons while oxidation requires the removal of electrons. If we used basic reagents, we could remove the OH proton from a primary alcohol, but to get the aldehyde we should have to remove a C–H proton as well with a pair of electrons. We should have to expel a hydride ion \( \text{H}^- \) and this doesn't happen. So we need some reagent that can remove a hydrogen atom and a pair of electrons. That defines an oxidizing agent.

Here Cr(VI) can remove electrons to make Cr(III). It does so by a cyclic mechanism on a Cr(VI) ester. One hydrogen atom is removed (from the OH group) to make the ester and the second is removed (from carbon) in the cyclic mechanism. Notice how the arrows stop on the Cr atom and start again on the Cr=O bond, so two electrons are added to the chromium. This actually makes Cr(IV), an unstable oxidation state, but this gives green Cr(III) by further reactions.

Two examples of the use of PCC in these oxidations come from Vogel. Hexanol is oxidized to hexanal in dichloromethane solution and commercial carveol (an impure natural product) to pure carvone with PCC supported on alumina in hexane solution. In both cases the pure aldehyde or ketone was isolated by distillation.

But a word of warning: stronger oxidizing agents like calcium hypochlorite or sodium hypochlorite (bleach) may oxidize primary alcohols all the way to carboxylic acids, especially in water. This is the case with \( p \)-chloro benzyl alcohol and the solid acid is easily isolated by the type of acid/base extraction we met in the previous chapter.

You will find further discussion of oxidizing agents in later chapters of the book. We have introduced them here so that you can see how primary and secondary alcohols, made by addition of organometallic reagents, can be oxidized to aldehydes or ketones so that the process can be repeated. A secondary alcohol, which could be made in two ways, can be oxidized with the pyridine–CrO\(_3\) complex to the ketone and reacted with any Grignard or organolithium compound to give a range of tertiary alcohols.
**Looking forward**

In this chapter we have covered interconversions between ketones, aldehydes, and alcohols by forming C–C bonds using organometallics. We looked at oxidation and reduction as ways of complementing these methods—you should now be able to suggest at least one way of making any primary, secondary, or tertiary alcohol from simple precursors. In the next two chapters we will broaden our horizons beyond aldehydes and ketones to look at the reactivity of other carbonyl compounds—carboxylic acids and their derivatives such as esters and amides—and other nucleophiles. But the idea that we study organic reactions not only for their own sake but also so we can use them to make things should stay with you. We will come back to how to design ways of making molecules in Chapter 28. Many of these methods will employ the organometallics you have just met. We will then devote Chapter 40 to a broader range of more complex organometallic methods.

**Further reading**

**Check your understanding**

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Nucleophilic substitution at the carbonyl group

You are already familiar with reactions of compounds containing carbonyl groups. Aldehydes and ketones react with nucleophiles at the carbon atom of their carbonyl group to give products containing hydroxyl groups. Because the carbonyl group is such a good electrophile, it reacts with a wide range of different nucleophiles: you have met reactions of aldehydes and ketones with (in Chapter 6) cyanide, water, and alcohols, and (in Chapter 9) organometallic reagents (organolithiums and organomagnesiums, or Grignard reagents).

In this chapter and Chapter 11 we shall look at some more reactions of the carbonyl group—and revisit some of the ones we touched on in Chapter 6. It is a tribute to the importance of this functional group for organic chemistry that we have devoted four chapters of this book to its reactions. Just like the reactions in Chapters 6 and 9, the reactions in Chapters 10 and 11 all involve attack of a nucleophile on a carbonyl group. The difference is that this step is followed by other mechanistic steps, which means that the overall reactions are not just additions but also substitutions.

The product of nucleophilic addition to a carbonyl group is not always a stable compound

Addition of a Grignard reagent to an aldehyde or ketone gives a stable alkoxide, which can be protonated with acid to produce an alcohol (you met this reaction in Chapter 9). The same is not true for addition of an alcohol to a carbonyl group in the presence of base—in Chapter 6 we drew a reversible, equilibrium arrow for this transformation and said that the product, a hemiacetal, is formed to a significant extent only if it is cyclic.

The reason for this instability is that RO$^-$ is easily expelled from the molecule. We call groups that can be expelled from molecules, usually taking with them a negative charge, leaving groups. We’ll look at leaving groups in more detail later in this chapter and again in Chapter 15.
Leaving groups

Leaving groups are anions such as Cl\(^-\), RO\(^-\), and RCO_2\(^-\) that can be expelled from molecules taking their negative charge with them.

So, if the nucleophile is also a leaving group, there is a chance that it will be lost again and that the carbonyl group will reform—in other words, the reaction will be reversible. The energy released in forming the C=O bond (bond strength 720 kJ mol\(^{-1}\)) makes up for the loss of two C–O single bonds (about 350 kJ mol\(^{-1}\) each), one of the reasons for the instability of the hemiacetal product in this case.

The same thing can happen if the starting carbonyl compound contains a potential leaving group. The unstable negatively charged intermediate in the red box below is formed when a Grignard reagent is added to an ester.

Again, it collapses with loss of RO\(^-\) as a leaving group. This time, though, we have not gone back to starting materials: instead we have made a new compound (a ketone) by a substitution reaction—the OR group of the starting material has been substituted by the Me group of the product. In fact the ketone product can react with the Grignard reagent a second time to give a tertiary alcohol. Later in this chapter we’ll discuss why the reaction doesn’t stop at the ketone.

Carboxylic acid derivatives

Most of the starting materials for, and products of, these substitutions will be carboxylic acid derivatives, with the general formula RCOX. You met the most important members of this class in Chapter 2: here they are again as a reminder.

Acid chlorides and acid anhydrides react with alcohols to make esters

Acetyl chloride will react with an alcohol in the presence of a base to give an acetate ester and we get the same product if we use acetic anhydride.
In each case, a substitution (of the black part of the molecule, $\text{Cl}^-$ or $\text{AcOO}^-$, by cyclohexanol) has taken place—but how? It is important that you learn not only the fact that acyl chlorides and acid anhydrides react with alcohols but also the mechanism of the reaction. In this chapter you will meet a lot of reactions, but relatively few mechanisms—once you understand one, you should find that the rest follow on quite logically.

The first step of the reaction is, as you might expect, addition of the nucleophilic alcohol to the electrophilic carbonyl group—we’ll take the acyl chloride first. The base is important because it removes the proton from the alcohol once it attacks the carbonyl group. A base commonly used for this is pyridine. If the electrophile had been an aldehyde or a ketone, we would have got an unstable hemiacetal, which would collapse back to starting materials by eliminating the alcohol. With an acyl chloride, the alkoxide intermediate we get is also unstable. It collapses again by an elimination reaction, this time losing chloride ion, to form the ester. Chloride is the leaving group here—it leaves with its negative charge.

With this reaction as a model, you should be able to work out the mechanism of ester formation from acetic anhydride and an alcohol. Try to write it down without looking at the acyl chloride mechanism above, and certainly not at the answer below. Here it is, with pyridine as the base. Again, addition of the nucleophile gives an unstable intermediate, which undergoes an elimination reaction, this time losing a carboxylate anion to give an ester.

We call the unstable intermediate formed in these reactions the tetrahedral intermediate because the trigonal ($sp^2$) carbon atom of the carbonyl group has become a tetrahedral ($sp^3$) carbon atom.

![Tetrahedral intermediates](image)

**Tetrahedral intermediates**
Substitutions at trigonal carbonyl groups go through a tetrahedral intermediate and then on to a trigonal product.
More details of this reaction

Acylation with acyl chlorides in the presence of pyridine has more subtleties than first meet the eye. If you are reading this chapter for the first time, you might skip this box, as it is not essential to the general flow of what we are saying. There are three more points to notice.

Pyridine is consumed during both of these reactions, since it ends up protonated. One whole equivalent of pyridine is therefore necessary and, in fact, the reactions are often carried out with pyridine as solvent.

The observant among you may also have noticed that the (weak—pyridine) base catalyst in this reaction works very slightly differently from the (strong—hydroxide) base catalyst in the hemiacetal-forming reaction on p. 197: pyridine removes the proton after the nucleophile has added; hydroxide removes the proton before the nucleophile has added. This is deliberate, and will be discussed further in Chapters 12 and 40. The basics of pyridine (pK\(_a\) for protonation 5.5) and hydroxide (pK\(_a\) of water 15.7) were discussed in Chapter 8.

Pyridine is, in fact, more nucleophilic than the alcohol, and it attacks the acyl chloride rapidly, forming a highly electrophilic (because of the positive charge) intermediate. It is then this intermediate that subsequently reacts with the alcohol to give the ester. Because pyridine is acting as a nucleophile to speed up the reaction, yet is unchanged by the reaction, it is called a nucleophilic catalyst.

Why are the tetrahedral intermediates unstable?

The alkoxide formed by addition of a Grignard reagent to an aldehyde or ketone is stable, lasting long enough to be protonated on work-up in acid to give an alcohol as product.

Tetrahedral intermediates are similarly formed by addition of a nucleophile, say ethanol in base, to the carbonyl group of acetyl chloride, but these tetrahedral intermediates are unstable. Why are they unstable? The answer is to do with leaving group ability. Once the nucleophile has added to the carbonyl compound, the stability of the product (or tetrahedral intermediate) depends on how good the groups attached to the new tetrahedral carbon atom are at leaving with the negative charge. In order for the tetrahedral intermediate to collapse (and therefore be just an intermediate and not the final product) one of the groups has to be able to leave and carry off the negative charge from the alkoxide anion formed in the addition.

The most stable anion will be the best leaving group. There were three choices for the leaving group: Cl\(^-\), EtO\(^-\), or Me\(^-\). We can make MeLi but not Me\(^-\) because it is very unstable so Me\(^-\) must be a very bad leaving group. EtO\(^-\) is not so bad—alkoxide salts are stable, but they are still strong, reactive bases. But Cl\(^-\) is the best leaving group: Cl\(^-\) ions are perfectly stable and quite unreactive, and happily carry off the negative charge from the oxygen atom.
You probably eat several grams of \( \text{Cl}^- \) every day but you would be unwise to eat \( \text{EtO}^- \) or \( \text{MeLi} \). So neither of these reactions occurs:

\[
\begin{align*}
\text{Cl}^- \text{OEt} & \quad \text{Me}^+ \quad \text{Cl}^- \text{OEt} \\
\end{align*}
\]

**How do we know that the tetrahedral intermediate exists?**

We don’t expect you to be satisfied with the bland statement that tetrahedral intermediates are formed in these reactions: of course, you wonder how we know that this is true. The first evidence for tetrahedral intermediates in the substitution reactions of carboxylic acid derivatives was provided by Bender in 1951. He made carboxylic acid derivatives \( \text{RCOX} \) that had been ‘labelled’ with an isotope of oxygen, \( ^{18}\text{O} \). This is a non-radioactive isotope that is detected by mass spectrometry. He then reacted these derivatives with water to make labelled carboxylic acids. By any reasonable mechanism, the products would have one \( ^{18}\text{O} \) atom from the labelled starting material. Because the proton on a carboxylic acid migrates rapidly from one oxygen to another, both oxygens are labelled equally.

He then reacted these derivatives with insufficient water for complete consumption of the starting material. At the end of the reaction, he found that the proportion of labelled molecules in the *remaining starting material* had decreased significantly: in other words, it was no longer completely labelled with \( ^{18}\text{O} \); some contained ‘normal’ \( ^{16}\text{O} \). The formation of the tetrahedral intermediate would be as before but rapid proton transfer would also mean that the two oxygen atoms would be the same. Now you may see the next step in the argument.

This result cannot be explained by direct substitution of \( \text{X} \) by \( \text{H}_2\text{O} \), but is consistent with the existence of an intermediate in which the unlabelled \( ^{16}\text{O} \) and labelled \( ^{18}\text{O} \) can ‘change places’. This intermediate is the *tetrahedral intermediate* for this reaction. Either isomer can lose \( \text{X} \) and in each case labelled carboxylic acid is formed.

But either tetrahedral intermediate could lose water instead. In one case (top line below) the original starting material is regenerated complete with label. But in the second case, labelled water is lost and *unlabelled starting material is formed*. This result would be difficult to explain without a tetrahedral intermediate with a lifetime long enough to allow for proton exchange. This ‘addition–elimination’ mechanism is now universally accepted.
pKa is a useful guide to leaving group ability

It’s useful to be able to compare leaving group ability quantitatively. This is impossible to do exactly, but a good guide is the pKₐ of the conjugate acid (Chapter 8). If X⁻ is the leaving group, the lower the pKₐ of HX, the better X⁻ is as a leaving group. If we go back to the example of ester formation from acyl chloride plus alcohol, there’s a choice of Me⁻, EtO⁻, and Cl⁻. HCl is a stronger acid than EtOH, which is a much stronger acid than methane. So Cl⁻ is the best leaving group and EtO⁻ the next best. These observations apply only to reactions at the carbonyl group.

Leaving group ability

The lower the pKₐ of HX, the better the leaving group of X⁻ in carbonyl substitution reactions.

The most important substituents in carbonyl reactions are alkyl or aryl groups (R), amino groups in amides (NH₂), alkoxy groups in esters (RO⁻), carboxylate groups (RCO₂⁻) in anhydrides, and chloride (Cl⁻) in acyl chlorides. The order of leaving group ability is then:

<table>
<thead>
<tr>
<th>carboxylic acid derivative</th>
<th>leaving group, X⁻</th>
<th>conjugate acid, HX</th>
<th>pKₐ of HX</th>
<th>leaving group?</th>
</tr>
</thead>

</tr>
</tbody>
</table>

We can use pKₐ to predict what happens if we react an acyl chloride with a carboxylate salt. We expect the carboxylate salt (here, sodium formate or sodium methanoate, HCO₂Na) to act as the nucleophile to form a tetrahedral intermediate, which could collapse in any one of three ways. We can straightaway rule out loss of Me⁻ and we might guess that Cl⁻ is a better leaving group than HCO₂⁻ as HCl is a much stronger acid than a carboxylic acid, and we’d be right. Sodium formate reacts with acetyl chloride to give a mixed anhydride.

Amines react with acyl chlorides to give amides

Using the principles we’ve outlined above, you should be able to see how these compounds can be interconverted by substitution reactions with appropriate nucleophiles. We’ve seen that acid chlorides react with carboxylic acids to give acid anhydrides, and with alcohols to give esters. They also react with amines (such as ammonia) to give amides.
The mechanism is very similar to the mechanism of ester formation. Notice the second molecule of ammonia, which removes a proton, and the loss of chloride ion—the leaving group—to form the amide. Ammonium chloride is formed as a by-product in the reaction.

Here is another example, using a secondary amine, dimethylamine. Try writing down the mechanism now without looking at the one above. Again, two equivalents of dimethylamine are necessary, although the chemists who published this reaction added three for good measure.

Schotten–Baumann synthesis of an amide
As these mechanisms show, the formation of amides from acid chlorides and amines is accompanied by production of one equivalent of HCl, which needs to be neutralized by a second equivalent of amine. An alternative method for making amides is to carry out the reaction in the presence of another base, such as NaOH, which then does the job of neutralizing the HCl. The trouble is, OH\(^-\) also attacks acyl chlorides to give carboxylic acids. Schotten and Baumann, in the late nineteenth century, published a way round this problem by carrying out these reactions in two-phase systems of immiscible water and dichloromethane. The organic amine (not necessarily ammonia) and the acyl chloride remain in the (lower) dichloromethane layer, while the base (NaOH) remains in the (upper) aqueous layer. Dichloromethane and chloroform are two common organic solvents that are heavier (more dense) than water. The acyl chloride reacts only with the amine, but the HCl produced can dissolve in, and be neutralized by, the aqueous solution of NaOH.

Using base strength to predict the outcome of substitution reactions of carboxylic acid derivatives
You saw that acid anhydrides react with alcohols to give esters: they will also react with amines to give amides. But would you expect esters to react with amines to give amides, or amides to react with alcohols to give esters? Both appear reasonable.
In fact only the top reaction works: amides can be formed from esters but esters cannot be formed from amides. The key question is: which group will leave from the common tetrahedral intermediate? The answer is MeO\(^-\) and not NH\(_2\)^-. You should have worked this out from the stability of the anions. Alkoxides are reasonably strong bases (pK\(_a\) of ROH about 15) so they are not good leaving groups. But NH\(_2\)^- is a very unstable anion (pK\(_a\) of NH\(_3\) about 25) and is a very bad leaving group.

So MeO\(^-\) leaves and the amide is formed. The base used to deprotonate the first formed intermediate may be either the MeO\(^-\) produced in the reaction or, to start with, another molecule of NH\(_3\).

Factors other than leaving group ability can be important

In fact, the tetrahedral intermediate would simply never form from an amide and an alcohol; the amide is too bad an electrophile and the alcohol not a good enough nucleophile. We’ve looked at leaving group ability: next we’ll consider the strength of the nucleophile Y and then the strength of the electrophile RCOX.

**Conditions for reaction**

If this reaction is to go:

1. X\(^-\) must be a better leaving group than Y\(^-\) (otherwise the reverse reaction would take place).
2. Y\(^-\) must be a strong enough nucleophile to attack RCOX.
3. RCOX must be a good enough electrophile to react with Y\(^-\).
Strength of nucleophile and leaving group ability are related and $pK_a$ is a guide to both

We have seen how $pK_a$ gives us a guide to leaving group ability: it is also a good guide to how strong a nucleophile will be. These two properties are the reverse of each other: good nucleophiles are bad leaving groups. A stable anion is a good leaving group but a poor nucleophile. Anions of weak acids (HA has high $pK_a$) are bad leaving groups but good nucleophiles towards the carbonyl group.

● Guide to nucleophilicity

*In general*, the higher the $pK_a$ of AH the better $A^-$ is as a nucleophile.

But just a moment—we’ve overlooked an important point. We have sometimes used anions as nucleophiles (for example when we made acid anhydrides from acid chlorides plus carboxylate salts, we used an anionic nucleophile $RCO_2^-$) but on other occasions we have used neutral nucleophiles (for example when we made amides from acid chlorides plus amines, we used a neutral nucleophile $NH_3$). Anions are better nucleophiles for carbonyl groups than are neutral compounds so we can choose our nucleophilic reagent accordingly.

For proper comparisons, we should use the $pK_a$ of $NH_4^+$ (about 10) if we are using neutral ammonia, but the $pK_a$ of $RCO_2H$ (about 5) if we’re using the carboxylate anion. Ammonia is a good nucleophile and we don’t usually need its anion but carboxylic acids are very weak nucleophiles and we often use their anions. You will see later in this chapter that we can alter this with acid catalysts. So this reaction works badly in either direction. We don’t make or hydrolyse esters this way.

![Chemical structures showing nucleophilicity and leaving group ability](Image)

While amines react with acetic anhydride quite rapidly at room temperature (reaction complete in a few hours), alcohols react extremely slowly in the absence of a base. On the other hand, an alkoxide anion reacts with acetic anhydride extremely rapidly—the reactions are often complete within seconds at 0 °C. We don’t have to deprotonate an alcohol completely to increase its reactivity: just a catalytic quantity of a weak base can do this job. All the $pK_a$s you need are in Chapter 8.

![Chemical structures showing nucleophilicity and leaving group ability](Image)

Not all carboxylic acid derivatives are equally reactive

We can list the common carboxylic acid derivatives in a ‘hierarchy’ of reactivity, with the most reactive at the top and the least reactive at the bottom. The nucleophile is the same in each case (water), as is the product, the carboxylic acid, but the electrophiles vary from very reactive to unreactive. The conditions needed for successful reaction show just how large is the variation on reactivity. Acid chlorides react violently with water. Amides need refluxing with 10% NaOH or concentrated HCl in a sealed tube at 100 °C overnight. We’ve seen that this hierarchy is partly due to how good the leaving group is (the ones at the top are best). But it also depends on the reactivity of the acid derivatives. Why is there such a large difference?
Delocalization and the electrophilicity of carbonyl compounds

Amides are the least reactive towards nucleophiles because they exhibit the greatest degree of delocalization. You met this concept in Chapter 7 and we shall return to it many times more. In an amide, the lone pair on the nitrogen atom can be stabilized by overlap with the \( \pi^* \) orbital of the carbonyl group—this overlap is best when the lone pair occupies a p orbital (in an amine, it would occupy an sp\(^3\) orbital).

The molecular orbital diagram shows how this interaction both lowers the energy of the bonding orbital (the delocalized nitrogen lone pair), making it neither basic nor nucleophilic, and raises the energy of the \( \pi^* \) orbital, making it less ready to react with nucleophiles. Esters are similar, but because the oxygen lone pairs are lower in energy, the effect is less pronounced. The degree of delocalization depends on the electron-donating power of the substituent and increases along the series of compounds below from almost no delocalization from Cl to complete delocalization in the carboxylate anion, where the negative charge is equally shared between the two oxygen atoms.

The greater the degree of delocalization, the weaker the C=O bond becomes. This is most clearly evident in the stretching frequency of the carbonyl group in the IR spectra of...
carboxylic acid derivatives—remember that the stretching frequency depends on the force constant of the bond, itself a measure of the bond’s strength. The carboxylate anion is included because it represents the limit of the series, with complete delocalization of the negative charge over the two oxygen atoms. There are two frequencies for the anhydride and the carboxylate anion because of symmetric and antisymmetric stretching of identical bonds.

Amides react as electrophiles only with powerful nucleophiles such as HO\textsuperscript{—}. Acid chlorides, on the other hand, react with even quite weak nucleophiles: neutral ROH, for example. They are more reactive because the electron-withdrawing effect of the chlorine atom increases the electrophilicity of the carbonyl carbon atom.

**Bond strengths and reactivity**

You may think that a weaker C=O bond should be more reactive. This is not so because the partial positive charge on carbon is also lessened by delocalization and because the molecule as a whole is stabilized by the delocalization. Bond strength is not always a good guide to reactivity!

For example, in acetic acid the bond strengths are surprising. The strongest bond is the O–H bond and the weakest is the C–C bond. Yet very few reactions of acetic acid involve breaking the C–C bond, and its characteristic reactivity, as an acid, involves breaking O–H; the strongest bond of them all!

The reason is that polarization of bonds and solvation of ions play an enormously important role in determining the reactivity of molecules. In Chapter 37 you will see that radicals are relatively unaffected by solvation and that their reactions follow bond strengths much more closely.

Infrared spectroscopy was introduced in Chapter 3.

**Carboxylic acids do not undergo substitution reactions under basic conditions**

Substitution reactions of RCO\textsubscript{2}H require a leaving group OH\textsuperscript{—}. The pK\textsubscript{a} of water is about 15, so acids should be about as electrophilic as esters. Esters react well with ammonia to give amides. However, if we try to react carboxylic acids with amines to give amides no substitution occurs: an ammonium salt is formed because the amines themselves are basic and remove the acidic proton from the acid.

Once the carboxylic acid is deprotonated, substitutions are prevented because (almost) no nucleophile will attack the carboxylate anion. Under neutral conditions, alcohols are just not reactive enough to add to the carboxylic acid but, with acid catalysis, esters can be formed from alcohols and carboxylic acids.

**Acid catalysts increase the reactivity of a carbonyl group**

We saw in Chapter 6 that the lone pairs of a carbonyl group may be protonated by acid. Only strong acids are powerful enough to protonate carbonyl groups: the pK\textsubscript{a} of protonated acetone is –7 so, for example, even 1M HCl (pH 0) would protonate only 1 in 10\textsuperscript{7} molecules of acetone. However, even proportions as low as this are sufficient to increase the rate of substitution reactions at carbonyl groups enormously because those carbonyl groups that are protonated become extremely powerful electrophiles.
the protonated carbonyl group
is a powerful electrophile

\[
\text{Nu} \quad \text{H} \quad \text{Nu} \quad \text{H} \quad \text{Nu} \quad \text{H}
\]

It is for this reason that alcohols will react with carboxylic acids under acid catalysis. The acid (usually HCl or H₂SO₄) reversibly protonates a small percentage of the carboxylic acid molecules, and the protonated carboxylic acids are extremely susceptible to attack by even a weak nucleophile such as an alcohol. This is the first half of the reaction:

acid-catalysed ester formation: forming the tetrahedral intermediate

\[
\text{Acid catalysts can make bad leaving groups into good ones}
\]

This tetrahedral intermediate is unstable because the energy to be gained by re-forming a C=O bond is greater than that used in breaking two C–O bonds. As it stands, none of the leaving groups (R−, HO−, or RO−) is very good. However, help is again at hand in the acid catalyst. It can protonate any of the oxygen atoms reversibly. Again, only a very small proportion of molecules are protonated at any one time but, once the oxygen atom of, say, one of the OH groups is protonated, it becomes a much better leaving group (water instead of HO−). Loss of ROH from the tetrahedral intermediate is also possible: this leads back to starting materials—hence the equilibrium arrow in the scheme above. Loss of H₂O is more fruitful, and takes the reaction forwards to the ester product.

acid-catalysed ester formation: decomposition of the tetrahedral intermediate

\[
\text{Ester formation is reversible: how to control an equilibrium}
\]

Loss of water from the tetrahedral intermediate is reversible too: just as ROH will attack a protonated carboxylic acid, H₂O will attack a protonated ester. In fact, every step in the sequence from carboxylic acid to ester is an equilibrium, and the overall equilibrium constant is about 1. In order for this reaction to be useful, it is therefore necessary to ensure that the equilibrium is pushed towards the ester side by using an excess of alcohol or carboxylic acid (usually the reactions are done in a solution of the alcohol or the carboxylic acid). In this reaction, for example, no water is added and an excess of alcohol is used. Using less than three equivalents of ethanol gave lower yields of ester.

\[
\begin{align*}
\text{ROH} & \quad \text{CO}_2\text{H} \quad \text{3 equiv. EtOH} \quad \text{dry HCl gas} \\
& \xrightarrow{68-72\% \text{ yield}} \\
\text{RO} & \quad \text{CO}_2\text{Et}
\end{align*}
\]
Alternatively, the reaction can be done in the presence of a dehydrating agent (concentrated H₂SO₄, for example, or silica gel) or the water can be distilled out of the mixture as it forms.

\[
\begin{align*}

\text{AcOH} & \quad \text{cat. H₂SO₄} \\
\text{silica gel (drying agent)} & \quad \text{OH} \\
\text{57% yield} & \quad \text{O} \\
\end{align*}
\]

● Making esters from alcohols
You have now met three ways of making esters from alcohols:
- with acyl chlorides
- with acid anhydrides
- with carboxylic acids.

Try to appreciate that different methods will be appropriate at different times. If you want to make a few milligrams of a complex ester, you are much more likely to work with a reactive acyl chloride or anhydride, using pyridine as a weakly basic catalyst, than to try to distil out a minute quantity of water from a reaction mixture containing a strong acid that may destroy the starting material. On the other hand, if you are a chemist making simple esters (such as those in Chapter 2, p. 31) for the flavouring industry on a scale of many tons, you might prefer the cheaper option of carboxylic acid and a strong acid (e.g. H₂SO₄) in alcohol solution.

Acid-catalysed ester hydrolysis and transesterification

By starting with an ester, an excess of water, and an acid catalyst we can persuade the reverse reaction to occur: formation of the carboxylic acid plus alcohol with consumption of water. Such a reaction is known as a hydrolysis reaction because water is used to break up the ester into carboxylic acid plus alcohol (lysis = breaking).

Acid-catalysed ester formation and hydrolysis are the exact reverse of one another: the only way we can control the reaction is by altering concentrations of reagents to drive the reaction the way we want it to go. The same principles can be used to convert an ester of one alcohol into an ester of another, a process known as transesterification. It is possible, for example, to force this equilibrium to the right by distilling methanol (which has a lower boiling point than the other components of the reaction) out of the mixture.

The mechanism for this transesterification simply consists of adding one alcohol (here BuOH) and eliminating the other (here MeOH), both processes being acid-catalysed. Notice how easy it is now to confirm that the reaction is catalytic in H⁺.
**Polyester fibre manufacture**

A transesterification reaction is used to make the polyester fibres that are used for textile production. Terylene, or Dacron, for example, is a polyester of the dicarboxylic acid terephthalic acid and the diol ethylene glycol.

![Interactive structure of polyester fibres]

Terylene is actually made by ester exchange: dimethyl terephthalate is heated with ethylene glycol and an acid catalyst, distilling off the methanol as it is formed.

**Base-catalysed hydrolysis of esters is irreversible**

You can’t make esters from carboxylic acids and alcohols under basic conditions because the base deprotonates the carboxylic acid (see p. 207). However, you can reverse that reaction and hydrolyse an ester to a carboxylic acid (more accurately, a carboxylate salt) and an alcohol.

![Interactive structure of ester hydrolysis]

This time the ester is, of course, not protonated first as it would be in acid, but the unprotonated ester is a good enough electrophile because $\text{OH}^-$, and not water, is the nucleophile. The tetrahedral intermediate can collapse either way, giving back ester or going forward to acid plus alcohol.
The backward reaction is impossible because the basic conditions straightaway deprotonate the acid to make a carboxylate salt (which, incidentally, consumes the base, making at least one equivalent of base necessary in the reaction). Carboxylate salts do not usually react with nucleophiles, even those a good deal stronger than alcohols.

**How do we know this is the mechanism?**

Ester hydrolysis is such an important reaction that chemists have spent a lot of time and effort finding out exactly how it works. Many of the experiments that tell us about the mechanism involve oxygen-18 labelling. The starting material is an ester enriched in the heavy oxygen isotope $^{18}$O. By knowing where the heavy oxygen atoms start off, and following (by mass spectrometry—Chapter 3) where they end up, the mechanism can be established.

1. An $^{18}$O label in the ‘ether’ oxygen of the ester ends up in the alcohol product.

   ![Diagram of ester hydrolysis](image)

2. Hydrolysis with $^{18}$OH$_2$ gives $^{18}$O-labelled carboxylic acid, but no $^{18}$O-labelled alcohol.

   ![Diagram of hydrolysis](image)

These experiments tell us that a displacement (substitution) has occurred at the carbonyl carbon atom, and rule out the alternative displacement at saturated carbon.

One further labelling experiment showed that a tetrahedral intermediate must be formed: an ester labelled with $^{18}$O in its carbonyl oxygen atom passes some of its $^{18}$O label to the water. We discussed this on p. 201. There is more on the mechanism of ester hydrolysis in Chapter 12.

The saturated fatty acid tetradecanoic acid (also known as myristic acid) is manufactured commercially from coconut oil by hydrolysis in base. You may be surprised to learn that coconut oil contains more saturated fat than butter, lard, or beef dripping: much of it is the trimyristate ester of glycerol. Hydrolysis with aqueous sodium hydroxide, followed by reprotonation of the sodium carboxylate salt with acid, gives myristic acid. Notice how much longer it takes to hydrolyse this branched ester than it did to hydrolyse a methyl ester (p. 210).
**Saponification**

The alkaline hydrolysis of esters to give carboxylate salts is known as saponification because it is the process used to make soap. Traditionally, beef tallow (the tristearate ester of glycerol—stearic acid is octadecanoic acid, C\(_{17}\)H\(_{35}\)CO\(_2\)H) was hydrolysed with sodium hydroxide to give sodium stearate, C\(_{17}\)H\(_{35}\)CO\(_2\)Na, the principal component of soap. Finer soaps are made from palm oil and contain a higher proportion of sodium palmitate, C\(_{15}\)H\(_{31}\)CO\(_2\)Na. Hydrolysis with KOH gives potassium carboxylates, which are used in liquid soaps. Soaps like these owe their detergent properties to the combination of polar (carboxylate group) and non-polar (long alkyl chain) properties.

**Amides can be hydrolysed under acidic or basic conditions too**

In order to hydrolyse amides, the least reactive of the carboxylic acid derivatives, we have a choice: we can persuade the amine leaving group to leave by protonating it, or we can use brute force and forcibly eject it with concentrated hydroxide solution.

Amides are very unreactive as electrophiles, but they are also rather more basic than most carboxylic acid derivatives: a typical protonated amide has a \(pK_a\) of \(-1\); most other carbonyl compounds are much less basic. You might therefore imagine that the protonation of an amide would take place on nitrogen—after all, amine nitrogen atoms are readily protonated. And, indeed, the reason for the basicity of amides is the nitrogen atom’s delocalized lone pair, making the carbonyl group unusually electron rich. But amides are always protonated on the oxygen atom of the carbonyl group, never the nitrogen, because protonation at nitrogen would disrupt the delocalized system that makes amides so stable. Protonation at oxygen gives a delocalized cation (Chapter 8).

Protonation of the carbonyl group by acid makes the carbonyl group electrophilic enough for attack by water, giving a neutral tetrahedral intermediate. The amine nitrogen atom in the tetrahedral intermediate is much more basic than the oxygen atoms, so now it gets protonated, and the RNH\(_2\) group becomes really quite a good leaving group. Once it has left, it will immediately be protonated again, and therefore become completely non-nucleophilic. The conditions are very vigorous—70% sulfuric acid for 3 hours at 100 °C.
Hydrolysis of amides in base requires similarly vigorous conditions. Hot solutions of hydroxide are sufficiently powerful nucleophiles to attack an amide carbonyl group, although even when the tetrahedral intermediate has formed NH$_2^-$ (pK$_a$ of the ammonium ion 35) has only a slight chance of leaving when HO$^-$ (pK$_a$ of water 15) is an alternative. Nonetheless, at high temperatures amides are slowly hydrolysed by concentrated base since one product is the carboxylate salt and this does not react with nucleophiles. The ‘base’ for the irreversible step might be hydroxide or NH$_2^-$.

Secondary and tertiary amides hydrolyse much more slowly under these conditions. With all these amides a second mechanism kicks in if the hydroxide concentration is large enough. More hydroxide deprotonates the tetrahedral anion to give a dianion that must lose NH$_2^-$ as the only alternative is O$^{2-}$. This leaving group deprotonates water so the second molecule of hydroxide ion is simply a catalyst.

Secondary and tertiary amides hydrolyse much more slowly under these conditions. With all these amides a second mechanism kicks in if the hydroxide concentration is large enough. More hydroxide deprotonates the tetrahedral anion to give a dianion that must lose NH$_2^-$ as the only alternative is O$^{2-}$. This leaving group deprotonates water so the second molecule of hydroxide ion is simply a catalyst.

A similar mechanism is successful with only a little water and plenty of strong base. Then even tertiary amides can be hydrolysed at room temperature. Potassium tert-butoxide is a strong enough base (pK$_a$ of t-BuOH about 18) to deprotonate the tetrahedral intermediate.

**Hydrolysing nitriles: how to make the almond extract, mandelic acid**

Closely related to the amides are nitriles. You can view them as primary amides that have lost one molecule of water and, indeed, they can be made by dehydrating primary amides.

They can be hydrolysed just like amides too. Addition of water to the protonated nitrile gives a primary amide, and hydrolysis of this amide gives carboxylic acid plus ammonia.
You met a way of making nitriles—from HCN (or NaCN + HCl) plus aldehydes—in Chapter 6: the hydroxynitrile products are known as cyanohydrins. With this in mind, you should be able to suggest a way of making mandelic acid, an extract of almonds, from benzaldehyde.

This is how some chemists did it.

Acid chlorides can be made from carboxylic acids using SOCl₂ or PCl₅

We have looked at a whole series of interconversions between carboxylic acid derivatives and, after this next section, we shall summarize what you need to understand. We said that it is always easy to move down the series of acid derivatives we listed early in the chapter, and so far that is all we have done. But some reactions of carboxylic acids also enable us to move upwards in the series. What we need is a reagent that changes the bad leaving group HO⁻ into a good leaving group. Strong acid does this by protonating the OH⁻, allowing it to leave as H₂O. In this section we look at two more reagents, SOCl₂ and PCl₅, which convert the OH group of a carboxylic acid and also turn it into a good leaving group. Thionyl chloride, SOCl₂, reacts with carboxylic acids to make acyl chlorides.

This volatile liquid with a choking smell is electrophilic at the sulfur atom (as you might expect with two chlorine atoms and an oxygen atom attached) and is attacked by carboxylic acids to give an unstable, and highly electrophilic, intermediate.

Reprotonation of the unstable intermediate (by the HCl just produced, i.e. reversal of the last step above) gives an electrophile powerful enough to react even with the weak nucleophile Cl⁻ (HCl is a strong acid, so Cl⁻ is a poor nucleophile). The tetrahedral intermediate collapses to the acyl chloride, sulfur dioxide, and hydrogen chloride. This step is irreversible because SO₂ and HCl are gases that are lost from the reaction mixture.
Although HCl is involved in this reaction, it cannot be used as the sole reagent for making acid chlorides. It is necessary to have a sulfur or phosphorus compound to remove the oxygen. An alternative reagent for converting RCO₂H into RCOCl is phosphorus pentachloride, PCl₅. The mechanism is similar—try writing it out before looking at the scheme below.

The mechanism is closely related to the previous one, except that the formation of a very stable P=O bond is the vital factor rather than the loss of two gaseous reagents.

These conversions of acids into acid chlorides complete all the methods we need to convert acids into any acid derivatives. You can convert acids directly to esters and now to acid chlorides, the most reactive of acid derivatives, and can make any other derivative from them. The chart below adds reaction conditions, relevant pKₐs, and infrared stretching frequencies to the reactivity order we met earlier.

All these acid derivatives can, of course, be hydrolysed to the acid itself with water alone or with various levels of acid or base catalysis depending on the reactivity of the derivative.
To climb the reactivity order therefore, the simplest method is to hydrolyse to the acid and convert the acid into the acid chloride. You are now at the top of the reactivity order and can go down to whatever level you require.

**Making other compounds by substitution reactions of acid derivatives**

We’ve talked at length about the interconversions of acid derivatives, explaining the mechanism of attack of nucleophiles such as ROH, H₂O, and NH₃ on acyl chlorides, acid anhydrides, esters, acids, and amines, with or without acid or base present. We shall now go on to talk about substitution reactions of acid derivatives that take us out of this closed company of compounds and allow us to make compounds containing functional groups at other oxidation levels, such as ketones and alcohols.

**Making ketones from esters: the problem**

Substitution of the OR group of an ester by an R group would give us a ketone. You might therefore think that reaction of an ester with an organolithium or Grignard reagent would be a good way of making ketones. However, if we try the reaction, something else happens, as you saw at the start of this chapter.

Two molecules of Grignard have been incorporated and we get an alcohol! If we look at the mechanism we can understand why this should be so. First, as you would expect, the nucleophilic Grignard reagent attacks the carbonyl group to give a tetrahedral intermediate. The only reasonable leaving group is \( \text{RO}^- \), so it leaves to give us the ketone we set out to make.

Now, the next molecule of Grignard reagent has a choice. It can react with either the ester starting material or the newly formed ketone. Ketones are more electrophilic than esters so the Grignard reagent prefers to react with the ketone in the manner you saw in Chapter 9. A stable alkoxide anion is formed, which gives the tertiary alcohol on acid work-up.

**Making alcohols instead of ketones**

In other words, the problem here lies in the fact that the ketone product is more reactive than the ester starting material. We shall meet more examples of this general problem later (in Chapter 23, for example): in the next section we shall look at ways of overcoming it. Meanwhile, why not see it as a useful reaction? This compound, for example, was needed by some chemists in the course of research into explosives.

It is a tertiary alcohol with the hydroxyl group flanked by two identical R (butyl) groups. The chemists who wanted to make the compound knew that an ester would react twice with the same organolithium reagent, so they made it from this unsaturated ester (known as methyl methacrylate) and butyllithium.
Tertiary alcohol synthesis

Tertiary alcohols with two identical \( R^2 \) groups can be made from ester \( R^1\text{CO}_2R \) plus two equivalents of organolithium \( R^2\text{Li} \) or Grignard reagent \( R^2\text{MgBr} \).

This reaction works in reduction too if we use lithium aluminium hydride, \( \text{LiAlH}_4 \). This is a powerful reducing agent that readily attacks the carbonyl group of an ester. Again, collapse of the tetrahedral intermediate gives a compound, this time an aldehyde, which is more reactive than the ester starting material, so a second reaction takes place and the ester is converted (reduced) into an alcohol. Sodium borohydride, often used for the reduction of ketones, does not usually reduce esters.

A bit of shorthand

Before we go any further, we should introduce to you a little bit of chemical shorthand that makes writing many mechanisms easier. As you now appreciate, all substitution reactions at a carbonyl group go via a tetrahedral intermediate.

A convenient way to save writing a step is to show the formation and collapse of the tetrahedral intermediate in the same structure, by using a double-headed arrow, as in the diagrams below. Now, this is a useful shorthand, but it is not a substitute for understanding the true mechanism. Certainly, you must never ever write the reaction as a single step not involving the carbonyl group.

Here’s the ‘shorthand’ at work in the \( \text{LiAlH}_4 \) reduction you have just met.
Making ketones from esters: the solution

We diagnosed the problem with our intended reaction as one of reactivity: the product ketone is more reactive than the starting ester. To get round this problem we need to do one of two things:

1. make the starting material more reactive or
2. make the product less reactive.

Making the starting materials more reactive

A more reactive starting material would be an acyl chloride: how about reacting one of these with a Grignard reagent? This approach can work—for example this reaction is successful.

\[
\text{MeO} \quad \text{Cl} \quad \text{O} \quad \text{OMe} \quad \xrightarrow{\text{MgBr}} \quad \text{OMe} \quad \text{O} \quad 81\% \text{ yield}
\]

Often, better results are obtained by transmetallating (see Chapter 9) the Grignard reagent, or the organolithium, with copper salts. Organocopper reagents are too unreactive to add to the product ketones, but they react well with the acyl chloride. Consider this reaction, for example: the product was needed for a synthesis of the antibiotic septamycin.

\[
\text{MeO} \quad \text{Me} \quad \text{Me} \quad \text{Cl} \quad \xrightarrow{\text{Me}_2\text{CuLi}} \quad \text{MeO} \quad \text{Me} \quad \text{Me} \quad 97\% \text{ yield}
\]

Making the products less reactive

This alternative solution is often better. With the right starting material, the tetrahedral intermediate can become stable enough not to collapse to a ketone during the reaction; it therefore remains completely unreactive towards nucleophiles. The ketone is formed only when the reaction is finally quenched with acid but the nucleophile is also destroyed by the acid and none is left for further addition.

\[
\begin{align*}
\text{R}_1 \quad \text{X} & \quad \xrightarrow{\text{R}_2\text{Li}} \quad \text{R}_1 \quad \text{O} \quad \text{R}_2 \\
\text{acid quench collapses the intermediate and simultaneously destroys unreacted organolithium}
\end{align*}
\]

We can illustrate this concept with a reaction of an unlikely looking electrophile, a lithium carboxylate. Towards the beginning of the chapter we said that carboxylic acids were bad electrophiles and that carboxylate salts were even worse. Well, that is true, but with a sufficiently powerful nucleophile (an organolithium) it is just possible to get addition to the carbonyl group of a lithium carboxylate.

We could say that the affinity of lithium for oxygen means that the Li–O bond has considerable covalent character, making the CO_2Li less of a true anion. And the intermediate after addition of MeLi is probably best represented as a covalent compound too. Anyway, the

Notice how this reaction illustrates the difference in reactivity between an acyl chloride functional group and an ester functional group.
product of this addition is a dianion of the sort that we met during one of the mechanisms of base-catalysed amide hydrolysis. But in this case there is no possible leaving group, so there the dianion sits. Only at the end of the reaction, when water is added, are the oxygen atoms protonated to give a hydrated ketone, which collapses immediately (remember Chapter 6) to give the ketone that we wanted. The water quench also destroys any remaining organolithium, so the ketone is safe from further attack.

This method has been used to make some ketones that are important starting materials for making cyclic natural products known as macrolides.

Another good set of starting materials that lead to non-collapsible tetrahedral intermediates is known as the Weinreb amides, after their inventor, S. M. Weinreb. Addition of organolithium or organomagnesium reagents to N-methoxy-N-methyl amides gives the tetrahedral intermediate shown, stabilized by chelation of the magnesium atom by the two oxygen atoms. Chelation means the coordination of more than one electron-donating atom in a molecule to a single metal atom.

This intermediate collapses to give a ketone only when acid is added at the end of the reaction.

The mechanism looks complicated but the reaction is easy to do:

This strategy even works for making aldehydes, if the starting material is dimethylformamide (DMF, Me₂NCHO). This is an extremely useful way of adding electrophilic CHO groups to organometallic nucleophiles. Once again, the tetrahedral intermediate is stable until acid is added at the end of the reaction and the protonated tetrahedral intermediate collapses.
A final alternative is to use a nitrile instead of an ester. The intermediate is the anion of an imine (see Chapter 12 for more about imines), which is not electrophilic at all—in fact, it’s quite nucleophilic, but there are no electrophiles for it to react with until the reaction is quenched with acid. It gets protonated and hydrolys (we’ll discuss this in the next chapter) to the ketone.

To summarize…

To finish, we should just remind you of what to think about when you consider a nucleophilic substitution at a carbonyl group.

And to conclude…

In this chapter you have been introduced to some important reactions—you can consider them to be a series of facts if you wish, but it is better to see them as the logical outcome of a few simple mechanistic steps. Relate what you have seen to what you gathered from Chapters 6 and 9, when we first started looking at carbonyl groups. All we did in this chapter was to build some subsequent transformations on to the simplest organic reaction, addition to a carbonyl group. You should have noticed that the reactions of all acid derivatives are related and are very easily explained by writing out proper mechanisms, taking into account the presence of acid or base. In the next two chapters we shall see more of these acid- and base-catalysed reactions of carbonyl groups. Try to view them as closely related to the ones in this chapter—the same principles apply to their mechanisms.

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at http://www.oxfordtextbooks.co.uk/orc/clayden2e/
Introduction

Nucleophiles add to carbonyl groups to give compounds in which the trigonal carbon atom of the carbonyl group has become tetrahedral.

In Chapter 10 you saw that these compounds are not always stable: if the starting material contains a leaving group, the addition product is a tetrahedral intermediate, which collapses with loss of the leaving group to give back the carbonyl group, with overall substitution of the leaving group by the nucleophile.

In this chapter you will meet substitution reactions of a different type. Instead of losing a leaving group, the carbonyl group loses its oxygen atom. Here are two important examples: the carbonyl oxygen atom has been replaced by a nitrogen atom during imine formation and by two atoms of oxygen during acetal formation. Notice too the acid catalyst—we shall see shortly why it is required. These are examples of nucleophilic substitution at the carbonyl group with loss of carbonyl oxygen.

Acetals had walk-on parts in Chapters 2 and 6; in this chapter they are one of the stars. They are simply compounds with two oxygen atoms bound to the same saturated carbon atom. This example is cyclic, but others are not, for example CH₂(OMe)₂.
You have, in fact, already met some less important reactions in which the carbonyl oxygen atom can be lost, but you probably didn’t notice at the time. The equilibrium between an aldehyde or ketone and its hydrate (p. 134) is one such reaction.

When the hydrate reverts to starting materials, either of its two oxygen atoms must leave: one came from the water and one from the carbonyl group, so 50% of the time the oxygen atom that belonged to the carbonyl group will be lost. Usually, this is of no consequence, but it can be useful. For example, in 1968 some chemists studying the reactions that take place inside mass spectrometers needed to label the carbonyl oxygen atom of a ketone with the isotope $^{18}$O.

By stirring the ‘normal’ $^{16}$O compound with a large excess of isotopically labelled water for a few hours in the presence of a drop of acid they were able to make the required labelled compound. Without the acid catalyst, the exchange is very slow. Acid catalysis speeds the reaction up by making the carbonyl group more electrophilic so that equilibrium is reached more quickly.

### Aldehydes can react with alcohols to form hemiacetals

When acetaldehyde is dissolved in methanol, a reaction takes place: we know this because the IR spectrum of the mixture shows that a new compound has been formed. Most dramatically, the carbonyl frequency is no longer there. However, isolating the product is impossible: it decomposes back to acetaldehyde and methanol.

The product is in fact a hemiacetal. Like hydrates, most hemiacetals are unstable with respect to their parent aldehydes and alcohols, for example the equilibrium constant for reaction of acetaldehyde with simple alcohols is about 0.5.

So by making [MeOH] very large (using it as the solvent, for example) we can turn most of the aldehyde into the hemiacetal. However, if we try to purify the hemiacetal by removing the methanol, more hemiacetal keeps decomposing to maintain the equilibrium constant. That is why we can never isolate such hemiacetals in a pure form.

### Acid or base catalysts increase the rate of equilibration of hemiacetals with their aldehyde and alcohol parents

Acyclic hemiacetals form relatively slowly from an aldehyde or ketone plus an alcohol, but their rate of formation is greatly increased either by acid or by base. As you would expect from Chapters 6 and 10, acid catalysts work by increasing the electrophilicity of the carbonyl group.
Base catalysts, on the other hand, work by increasing the nucleophilicity of the alcohol by removing the OH proton before it attacks the C=O group. In both cases the energy of the starting materials is raised: in the acid-catalysed reaction the aldehyde is destabilized by protonation and in the base-catalysed reaction the alcohol is destabilized by deprotonation.

You can see why hemiacetals are unstable: they are essentially tetrahedral intermediates containing a leaving group and, just as acid or base catalyses the formation of hemiacetals, acid or base also catalyses their decomposition back to starting aldehyde or ketone and alcohol. That’s why the title of this section indicated that acid or base catalysts increase the rate of equilibration of hemiacetals with their aldehyde and alcohol components—catalysts never change the position of that equilibrium!

To summarize

Hemiacetal formation and decomposition are catalysed by acid or base.

Acetals are formed from aldehydes or ketones plus alcohols in the presence of acid

We said that a solution of acetaldehyde in methanol contains a new compound: a hemiacetal. We’ve also said that the rate of formation of hemiacetals is increased by adding an acid (or a base) catalyst to the alcohol plus aldehyde mixture. But, if we add catalytic acid to our acetaldehyde–methanol mixture, we find not only that the rate of reaction of the acetaldehyde with the methanol increases, but also that a different product is formed. This product is an acetal; the hemiacetal is half-way there.

In the presence of acid (but not base!) hemiacetals can undergo an elimination reaction (different from the one that just gives back aldehyde plus alcohol), losing the oxygen atom that once belonged to the parent aldehyde’s carbonyl group.
The stages are:

1. Protonation of the hydroxyl group of the hemiacetal.
2. Loss of water by elimination. This elimination leads to an unstable and highly reactive oxonium ion.
3. Addition of methanol to the oxonium ion (breaking the π bond and not the σ bond, of course).
4. Loss of a proton to give the acetal.

Oxonium ions

Oxonium ions have three bonds to a positively charged oxygen atom. All three bonds can be σ bonds, as in H$_3$O$^+$ or Meerwein’s salt, trimethyloxonium tetrafluoroborate, a stable (though reactive) alkylating agent, or one bond can be a π bond as in the acetal intermediate. The term ‘oxonium ion’ describes either of these structures. They are like alkylated ethers or O-alkylated carbonyl compounds.

Just as protonated carbonyl groups are much more electrophilic than unprotonated ones, these oxonium ions are powerful electrophiles. They can react rapidly with a second molecule of alcohol to form the new, stable compounds known as acetals. An oxonium ion was also an intermediate in the formation of hemiacetals in acid solution. Before reading any further, it would be worthwhile to write out the whole mechanism of acetal formation from aldehyde or ketone plus alcohol through the hemiacetal to the acetal, preferably without looking at the fragments of mechanism above or the answer overleaf.

Formation of acetals and hemiacetals

Hemiacetal formation is catalysed by acid or base, but acetal formation is possible only with an acid catalyst because an OH group must be made into a good leaving group.

The mechanism is the most complex you have met and it will help you to recall it if you see it in two halves, each very similar to the other. The reaction starts with a protonation on carbonyl oxygen and addition of an alcohol to the C=O π bond. When you get to the temporary haven of the hemiacetal, you start again with protonation of that same oxygen then lose the OH group by breaking what was the C=O σ bond to form an oxonium ion. Each half goes through an oxonium ion and the alcohol adds to each oxonium ion. The last step in the formation of both the acetal and the hemiacetal is the loss of a proton from the recently added alcohol. From your complete mechanism you should also be able to verify that acetal formation is indeed catalytic in acid.
Interactive mechanism for acetal formation

- Remember the oxonium ion!

When you wrote out your mechanism for acetal formation, we hope you didn’t miss out the oxonium ion! It’s easy to do so, but the mechanism most definitely does not go via a direct displacement of water by alcohol.

If you wonder how we know this, consult a specialized book on organic reaction mechanisms. After you have read Chapter 15 in this book, you will be able to spot that this substitution step goes via an $SN_1$ and not an $SN_2$ mechanism.

Making acetals

Just as with the ester formation and hydrolysis reactions we discussed in Chapter 10, every step in the formation of an acetal is reversible. To make acetals, therefore, we must use an excess of alcohol or remove the water from the reaction mixture as it forms, by distillation for example.

In fact, acetal formation is even more difficult than ester formation: while the equilibrium constant for acid-catalysed formation of ester from carboxylic acid plus alcohol is usually about 1, for acetal formation from an aldehyde and ethanol (shown above), the equilibrium constant is $K = 0.0125$. For ketones, the value is even lower: in fact, it is often very difficult to make the acetals of ketones (sometimes called ketals) unless they are cyclic (we consider cyclic acetics later in the chapter). However, there are several techniques that can be used to prevent the water produced in the reaction from hydrolysing the product.
para-Toluenesulfonic acid

para-Toluenesulfonic acid is commonly used to catalyse reactions of this sort. It is a stable solid, yet is as strong an acid as sulfuric acid. It is widely available and cheap because it is produced as a by-product in the synthesis of saccharin (for more details, see Chapter 21).

With the more reactive aldehyde, it was sufficient just to have an excess of one of the reagents (acetaldehyde) to drive the reaction to completion. Dry HCl gas can work too. With a less reactive ketone, molecular sieves (zeolite) were used to remove water from the reaction as it proceeded.

Acetals hydrolyse only in the presence of acid

Just as acetal formation requires acid catalysis, acetals can be hydrolysed only by using an acid catalyst. With aqueous acid, the hydrolysis of acyclic acetals is very easy. Our examples are the two acetals we made earlier.

We won’t go through the mechanism again—you’ve already seen it as the reverse of acetal formation, but the fact that acetals are stable to base is really a very important point, which we will use on the next page and capitalize on further in Chapter 23.

Cyclic acetals are more stable than acyclic acetals

Of course you want us to prove it. Well, in this example the starting material has three acetals: an ordinary acetal formed from methanol (in black), a five-membered cyclic acetal, and a dithioacetal. Only the black acetal hydrolyses under these mild conditions.

The acetals you have met so far were formed by reaction of two molecules of alcohol with one of carbonyl compound. Cyclic acetals, formed by reaction of a single molecule of a diol, a compound containing two hydroxyl groups, are also important. When the diol is ethylene glycol (as in this example) the five-membered cyclic acetal is known as a dioxolane.
Before looking at the answer below, try to write a mechanism for this reaction. If you need it, use the mechanism we gave for the formation of acyclic acetals.

Water is still generated, and needs to be got rid of: in the example above you can see that water was distilled out of the reaction mixture. This is possible with these diols because they have a boiling point above that of water (the boiling point of ethylene glycol is 197 °C). You can’t distil water from a reaction mixture containing methanol or ethanol because the alcohols distil too! One very useful piece of equipment for removing water from reaction mixtures containing only reagents that boil at higher temperatures than water is called a Dean Stark head.

**Dean Stark head**

When a mixture of toluene and water boils, the vapour produced is a constant ratio mixture of toluene vapour and water vapour known as an **azeotrope**. If this mixture is condensed, the liquid toluene and water, being immiscible, separate out into two layers with the water below. By using a Dean Stark apparatus, or Dean Stark head, the toluene layer can be returned to the reaction mixture while the water is removed. Reactions requiring removal of water by distillation are therefore often carried out in refluxing toluene or benzene under a Dean Stark head.

**Modifying reactivity using acetals**

Why are acetals so important? Well, they’re important to both nature and chemists because many carbohydrates are acetals or hemiacetals (see the box below). One important use that chemists have put them to is as **protecting groups**. One synthesis of the steroid class of compounds (about which more later) requires a Grignard reagent with an impossible structure. This compound cannot exist as the Grignard functional group would attack the ketone: it would react with itself. Instead, the protected Grignard reagent is used, made from the same bromoketone, but with an acetal-forming step.

Acetals, as we stressed, are stable to base and to basic nucleophiles such as Grignard reagents, so we no longer have a reactivity problem. Once the Grignard reagent has reacted with an electrophile, the ketone can be recovered by hydrolysing the acetal in dilute acid. The acetal is functioning here as a protecting group because it protects the ketone from attack by the Grignard reagent. Protecting groups are extremely important in organic synthesis and we will return to them in Chapter 23.
**Acetals in nature**

We showed you glucose as on p.137 an example of a stable, cyclic hemiacetal. Glucose can, in fact, react with itself to form an acetal known as maltose. Maltose is a disaccharide (made of two sugar units) produced by the enzymatic hydrolysis of starch or cellulose, which are themselves polyacetals made up of a string of glucose units.

**Amines react with carbonyl compounds**

The ketone carbonyl group of pyruvic acid (or 2-oxopropanoic acid) has a stretching frequency of a typical ketone, 1710 cm\(^{-1}\). When hydroxylamine is added to a solution of pyruvic acid, this stretching frequency slowly disappears. Later, a new IR absorption appears at 1400 cm\(^{-1}\). What happens?

You can probably apply something of what you know from Chapters 6 and 10 about the reactivity of carbonyl compounds towards nucleophiles to work out what is happening in this reaction between a carbonyl compound and an amine. The hydroxylamine first adds to the ketone to form an unstable intermediate similar to a hemiacetal.

Notice that it is the more nucleophilic nitrogen atom, and not the oxygen atom, of hydroxylamine that adds to the carbonyl group. Like hemiacetals, these intermediates are unstable and can decompose by loss of water. The product is known as an oxime and it is this compound, with its C=\(\equiv\)N double bond, that is responsible for the IR absorption at 1400 cm\(^{-1}\).
We know that the oxime is formed via an intermediate because the 1400 cm\(^{-1}\) absorption hardly appears until after the 1710 cm\(^{-1}\) absorption has almost completely gone. There must really be another curve to show the formation and the decay of the intermediate. The only difference is that the intermediate has no double bond to give an IR absorbance in this region of the spectrum. We come back to oximes later in the chapter.

**Imines are the nitrogen analogues of carbonyl compounds**

In fact, the oxime formed from a ketone and hydroxylamine is just a special example of an imine. All imines have a C=\(\text{N}\) double bond and are formed when any primary amine reacts with an aldehyde or a ketone under appropriate conditions, for example aniline and benzaldehyde.

You shouldn’t need us to tell you the mechanism of this reaction: even without looking at the mechanism we gave for the formation of the oxime it should come as no surprise to you by now. But as the reaction is very important in chemistry and biology, we’ll discuss it in some depth. First, the amine attacks the aldehyde and the intermediate known as a hemiacetal is formed. Amines are good nucleophiles for carbonyl groups, and aldehydes and ketones are electrophilic. There is no need for any catalysis in this step. Indeed, addition of acid would slow the reaction down as the nucleophilic amine would be removed as a salt.

**First step in imine formation:**
the amine attacks the carbonyl group to form the hemiaminal intermediate:

Dehydration of the hemiaminal gives the imine. Now there is some need for catalysis: acid must be added so that the OH group can become a good leaving group. This step resembles the conversion of hemiacetals to acetals. The difference is that the iminium ion can lose a proton and become a neutral imine.
Imine formation requires acid catalysis.

So acid is needed for the second step but hinders the first step. Clearly some compromise is needed. Without an acid catalyst, the reaction is very slow, although in some cases it may still take place. Imine formation is in fact fastest at about pH 4–6: at lower pH, too much amine is protonated and the rate of the first step is slow; above this pH the proton concentration is too low to allow protonation of the OH leaving group in the dehydration step. Imine formation is like a biological reaction: it is fastest near neutrality.

Imines are usually unstable and are easily hydrolysed

Like acetals, imines are unstable with respect to their parent carbonyl compound and amine, and must be formed by a method that allows removal of water from the reaction mixture.

Imines are formed from aldehydes or ketones with most primary amines. In general, they are stable enough to be isolated only if either the C or N of the imine double bond bears an aromatic substituent. Imines formed from ammonia are unstable, but can be detected in solution. CH$_2$=NH, for example, decomposes at temperatures above ~80 °C, but PhCH=NH is detectable by UV spectroscopy in a mixture of benzaldehyde and ammonia in methanol.

Imines are readily hydrolysed to the carbonyl compound and amine by aqueous acid—in fact, except for the particularly stable special cases we discuss below, most can be hydrolysed by water without acid or base catalysis. You have, in fact, already met an imine hydrolysis: at the end of Chapter 10 we talked about the addition of Grignard reagents to nitriles. The product is an imine that hydrolyses in acid solution to ketone plus ammonia.

The mechanism of the hydrolysis is the reverse of imine formation, going through the same hemiaminal intermediate and the same iminium and oxonium ions. All these steps are reversible and this should remind you that the relative stability of the starting material and product is as important in imine formation and hydrolysis as it is in acetal formation and hydrolysis.
Some imines are stable

Imines in which the nitrogen atom carries an electronegative group are usually stable: examples include oximes, hydrazones, and semicarbazones.

These compounds are more stable than imines because the electronegative substituent can participate in delocalization of the imine double bond. Delocalization decreases the small positive charge on the carbon atom of the imine double bond and raises the energy of the LUMO, making it less susceptible to nucleophilic attack. Oximes, hydrazones, and semicarbazones require acid or base catalysis to be hydrolysed.

Historical note

Because the hydrazone and semicarbazone derivatives of carbonyl compounds are often stable, crystalline solids, they used to be used to confirm the supposed identity of aldehydes and ketones. For example, the boiling points of these three isomeric five-carbon ketones are all similar and before the days of NMR spectroscopy it would have been hard to distinguish between them.

Their semicarbazones and 2,4-dinitrophenylhydrazones, on the other hand, all differ in their melting points. By making these derivatives of the ketones, identification was made much easier. Of course, all of this has been totally superseded by NMR! However, these crystalline derivatives are still useful in the purification of volatile aldehydes and ketones, and in solving structures by X-ray crystallography.
**Iminium ions and oxonium ions**

Let’s return to the mechanism of imine formation, and compare it for a moment with that of acetal formation. The only difference to begin with is that there is no need for acid catalysis for the addition of the amine but there is need for acid catalysis in the addition of the alcohol, a much weaker nucleophile.

\[
\begin{align*}
&\text{acid-catalysed imine formation} \\
&\text{hemiaminal intermediate} \\
&\text{iminium ion} \\
&\text{acid-catalysed acetal formation} \\
&\text{hemiacetal intermediate} \\
&\text{oxonium ion}
\end{align*}
\]

Up to this point, the two mechanisms follow a very similar path, with clear analogy between the hemiaminal and hemiacetal intermediates, and between the iminium and oxonium ions. Here, though, they diverge, because the iminium ion carries a proton, which the oxonium ion doesn’t have. The iminium ion therefore acts as an acid, losing a proton to become the imine. The oxonium ion, on the other hand, acts as an electrophile, adding another molecule of alcohol to become the acetal.

\[
\begin{align*}
&\text{iminium ion} \\
&\text{oxonium ion} \\
&\text{imine} \\
&\text{acetal}
\end{align*}
\]

As you might guess, however, iminium ions can be persuaded to act as electrophiles, just like oxonium ions, provided a suitable nucleophile is present. We will spend the next few pages considering reactions in which an iminium ion acts as an electrophile. First, though, we will look at a reaction in which the iminium ion cannot lose an N–H proton because it has none.

**Secondary amines react with carbonyl compounds to form enamines**

Pyrrolidine, a secondary amine, reacts with isobutyraldehyde, under the sort of conditions you would use to make an imine, to give an enamine. The name enamine combines ‘ene’ (C=C double bond) and ‘amine’.

\[
\begin{align*}
&\text{TsOH catalyst} \\
&\text{benzene, heat} \\
&\text{H}_2\text{O (Dean Stark)} \\
&\text{ene amine}
\end{align*}
\]

The mechanism consists of the same steps as those that take place when imines form from primary amines, up to formation of the iminium ion. This iminium ion has no N–H proton to lose, so it loses one of the C–H protons next to the C=N to give the enamine. Enamines, like imines, are unstable to aqueous acid.

\[
\begin{align*}
&\text{secondary amine} \\
&\text{(pyrrolidine)} \\
&\text{enamine}
\end{align*}
\]
Imines and enamines

- Imines are formed from aldehydes or ketones with primary amines.
- Enamines are formed from aldehydes or ketones with secondary amines.

Both require acid catalysis and removal of water.

Enamines of primary amines, or even of ammonia, also exist, but only in equilibrium with an imine isomer. The interconversion between imine and enamine is the nitrogen analogue of enolization, which is discussed in detail in Chapter 20.

Iminium ions can react as electrophilic intermediates

We made the point above that the difference in reactivity between an iminium ion and an oxonium ion is that an iminium ion can lose H⁺ and form an imine or an enamine, while an oxonium ion reacts as an electrophile. Iminium ions can, however, react as electrophiles provided suitable nucleophiles are present. In fact, they are very good electrophiles, and are significantly more reactive than carbonyl compounds. For example, iminium ions are reduced rapidly by the mild reducing agent sodium cyanoborohydride, Na(CN)BH₃, while carbonyl compounds are not. An alternative to Na(CN)BH₃ is NaBH(OAc)₃ (sodium triacetoxyborohydride)—somewhat safer because strong acid can release deadly HCN from Na(CN)BH₃.

Amines from imines: reductive amination

A useful way of making amines is by reduction of imines (or iminium ions). This overall process, from carbonyl compound to amine, is called reductive amination. This is, in fact, one of the few successful ways, and the best way, of making secondary amines. This should be your first choice in amine synthesis.

This can be done in two steps, provided the intermediate is stable, but, because the instability of many imines makes them hard to isolate, the most convenient way of doing it is to form and reduce the imine in a single reaction. The selective reduction of iminium ions (but not carbonyl compounds) by sodium cyanoborohydride makes this possible. When Na(CN)BH₃ is added to a typical imine-formation reaction it reacts with the iminium ion but not with the starting carbonyl compound nor with the imine. Here is an example of an amine synthesis using reductive amination.
In the first step, the ketone and ammonia are in equilibrium with their imine, which, at pH 6, is partly protonated as an iminium ion. The iminium ion is rapidly reduced by the cyanoborohydride to give the amine. Reactions like this, using ammonia in a reductive amination, are often carried out with ammonium chloride or acetate as convenient sources of ammonia. At pH 6, ammonia will be mostly protonated anyway as the pKₐ of NH₄⁺ is about 10.

Ph Me
O
NH₂ pH 6

In the second step of the synthesis, amine plus formaldehyde gives an imine, present as its protonated iminium form, which gets reduced. Formaldehyde is so reactive that it reacts again with the secondary amine to give an iminium ion; this too is reduced to the amine.

HC N
OH
pyridoxal

This imine (biochemists call imines Schiff bases) is in equilibrium with an isomeric imine, which can be hydrolysed to pyridoxal and alanine. These reactions are, of course, all controlled by enzymes and coupled to the degradation of unwanted amino acids (the latter process converts the pyridoxal back to pyridoxamine). Nature was doing reductive aminations a long time before sodium cyanoborohydride was invented! We will come back to this in Chapter 42.

An alternative method for reductive amination uses hydrogenation (hydrogen gas with a metal catalyst) to reduce the imine in the presence of the carbonyl compound. Most of these reductions do not require such high temperatures or pressures.

Ph CHO
NH₂ 70 °C 90 atm.
NH₃

Hydrogenation is a good way of reducing a number of different functional groups, but not (usually) carbonyl groups. In Chapter 23 we will look in more detail at reducing agents (and other types of reagent) that demonstrate selectivity for one functional group over another (chemoselectivity).
Lithium aluminium hydride reduces amides to amines

We’ve talked about reduction of iminium ions formed from carbonyl compounds plus amines. Iminium ions can also be formed by reducing amides with lithium aluminium hydride. A tetrahedral intermediate is formed that collapses to the iminium ion.

The iminium ion is, of course, more electrophilic than the starting amides (amide carbonyl groups are about the least electrophilic of any!), so it gets reduced to the secondary amine. This reaction can be used to make secondary amines from primary amines and acyl chlorides. A similar reduction with lithium aluminium hydride gives a primary amine from a nitrile.

Cyanide will attack iminium ions: the Strecker synthesis of amino acids

Cyanide will react with iminium ions to form α amino nitriles. Although these compounds are relatively unimportant in their own right, a simple hydrolysis step produces α amino acids. This route to amino acids is known as the Strecker synthesis. Of course, it’s not usually necessary to make the amino acids that Nature produces for us in living systems: they can be extracted from hydrolysed proteins. This Strecker synthesis is of phenylglycine, an amino acid not found in proteins. Cyanide reacts more rapidly with the iminium ion generated in the first step than it does with the starting benzaldehyde.

The synthesis of a spider toxin: reductive amination

This compound is the toxin used by the orb weaver spider to paralyse its prey. Notice that it has a guanidine at its right-hand end. These are stable imines, and their powerful basicity was discussed in Chapter 8. Since the spider produces only minute quantities of the compound, chemists at the University of Bath set about synthesizing it in the laboratory so that they could study its biological properties. The toxin contains several amide and amine functional groups, and the chemists decided that the best way to make it was to link two molecules together at one of the secondary amine groups using a reductive amination.
Substitution of C=O for C=C: a brief look at the Wittig reaction

Before we leave substitution reactions of carbonyl groups, there is one more reaction that we must introduce. It is an important one and we will come back to it again later in this book, particularly in Chapter 27. It also has a rather different mechanism from most you have met in recent chapters, but we talk about it here because the overall consequence of the Wittig reaction is the substitution of a C=C bond for a C=O bond.

We don’t normally tell you the name of a reaction before even mentioning how to do it, but here we make an exception because the reagents are rather unusual and need explaining in detail. The Wittig reaction is a reaction between a carbonyl compound (aldehyde or ketone only) and a species known as a phosphonium ylid. An ylid (or ylide) is a species with positive and negative charges on adjacent atoms, and phosphonium ylids are made from phosphonium salts by deprotonating them with a strong base.

You have already met phosphonium salts in Chapter 5, where you saw the reaction of a phosphine (triphenylphosphine) with an alkyl halide (methyl iodide) to give the tetrahedral phosphonium salt.

So here is a typical Wittig reaction: it starts with a phosphonium salt, which is treated with a strong base such as BuLi or sodium hydride, and then with a carbonyl compound; the alkene forms in 85% yield.

What about the mechanism? We warned you that the mechanism is rather different from all the others you have met in this chapter, but nonetheless it begins with attack on the
carbonyl group by a nucleophile; the nucleophile is the carbanion part of the phosphonium ylid. This reaction generates a negatively charged oxygen that attacks the positively charged phosphorus and gives a four-membered ring called an oxaphosphetane.

Now, this four-membered ring (like many others) is unstable, and it can collapse in a way that forms two double bonds. Here are the curly arrows: the mechanism is cyclic and gives the alkene, which is the product of the reaction along with a phosphine oxide.

The chemistry of some elements is dominated by one particular property, and a theme running right through the chemistry of phosphorus is its exceptional affinity for oxygen. The $\text{P} = \text{O}$ bond, with its bond energy of 575 kJ mol$^{-1}$, is one of the strongest double bonds in chemistry, and the Wittig reaction is irreversible and is driven forward by the formation of this $\text{P} = \text{O}$ bond. No need here for the careful control of an equilibrium necessary when making acetals or imines.

**Summary**

In this chapter, as in Chapter 10, you have met a wide variety of reactions, but we hope you have again been able to see that they are all related mechanistically. Of course, we have not been exhaustive: it would be impossible to cover every possible reaction of a carbonyl group, but having read Chapters 6, 9, and 10 you should feel confident in writing a *reasonable mechanism* for any reaction involving nucleophilic attack on a carbonyl group. You could try thinking about this, for example.

In the next chapter we examine in a little more detail the phrase ‘a reasonable mechanism’: how do we know what mechanisms are reasonable, and what can we do to understand them? We shall look in more detail at some of the topics raised in this chapter, such as equilibria and rates of reactions. Carbonyl groups next star in Chapter 20 where they reveal a thus far hidden nucleophilic side to their character.
Further reading

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
If you go into a chemistry laboratory, you will see some reactions being heated in boiling solvent (perhaps 80 to 120 °C), and you will see others being performed at maybe –80 °C or below. Some reactions are over in a few minutes; others are left for hours. In some reactions the amounts of reagents are critical; in others large excesses are used. Some reactions use water as a solvent; in others it must be rigorously excluded, and perhaps toluene, ether, ethanol, or DMF is essential for the success of the reaction. Why such a diverse range of conditions? How can conditions be chosen to favour the reaction we want? To explain all this we will need to work through some thermodynamic principles. We will take a practical, visual approach to the topic, and we will avoid detailed algebraic discussion: for that you are welcome to turn to a textbook of physical chemistry—there are some suggestions at the end of this chapter. In fact, we will use only two algebraic equations. Both are so important that you should memorize them; the second in particular can be extremely valuable when we think about how to get reactions to work.

How far and how fast?

In previous chapters we have said things about the reversibility of reactions:

‘Cyanohydrin formation is reversible: just dissolving a cyanohydrin in water can give back the aldehyde or ketone you started with’ (Chapter 6); ‘HCl transfers its proton almost completely to water, and is a strong acid. But the transfer of protons to water from carboxylic acids is only partial’ (Chapter 8); ‘This step is irreversible because SO₂ and HCl are gases that are lost from the reaction mixture’ (Chapter 10); ‘The tetrahedral intermediate can collapse either way, giving back ester or going forward to acid plus alcohol.’ (Chapter 10);

Note: The equation relating Gibbs free energy with the equilibrium constant appears incorrectly throughout this edition. The correct equation is $\Delta G^0 = -RT \ln K$, where the small circle denotes substances in their standard state (solutions at 1 M and gases at 1 bar partial pressure). For the change in Gibbs free energy in general, the correct equation is $\Delta G = RT \ln Q/K$, where $Q$ is the reaction quotient. For any system at equilibrium, $\Delta G = 0$.
about the relative stability of different compounds:

‘The most important factor in the strength of an acid is the stability of the conjugate base’ (Chapter 8); ‘F⁻ is much more stable than CH₃⁻ because fluorine is much more electronegative than carbon’ (Chapter 8); ‘Oximes are more stable than imines because the electronegative substituent can participate in delocalization of the imine double bond’ (Chapter 11);

and about the rate of reactions:

‘Benzaldehyde is reduced about 400 times faster than acetophenone in isopropanol’ (Chapter 6); ‘While amines react with acetic anhydride quite rapidly at room temperature (reaction complete in a few hours), alcohols react extremely slowly in the absence of a base’ (Chapter 10); ‘Secondary and tertiary amides are difficult to hydrolyse but a similar mechanism is successful with only a little water and plenty of a strong base’ (Chapter 10); ‘Acyclic hemiacetals form relatively slowly from an aldehyde or ketone plus an alcohol, but their rate of formation is greatly increased either by acid or by base’ (Chapter 11).

We are now going to consider in detail why some reactions can run forwards or backwards, why some form products irreversibly, why some reach an equilibrium, why some reactions go fast and some go slow, and what stability has to do with all of this. Understanding these factors will allow you to make the reactions you want to happen go faster and the reactions you don’t want to happen go slower, giving you a product in a useful yield. We shall be breaking reaction mechanisms down into steps and working out which step is the most important. But first we must consider what we really mean by the ‘stability’ of molecules and what determines how much of one substance you get when it is in equilibrium with another.

Stability and energy levels

So far we have been rather vague about the term ‘stability’, just saying things like ‘this compound is more stable than that compound’. What we really mean is that this compound has less energy than that one. For example, as you know from Chapters 4 and 7 alkenes can come in two forms we can call cis and trans. In general trans-alkenes are more stable than cis-alkenes. How do we know? Well, we can convert both cis- and trans-butene to the same alkane, butane, by adding a molecule of hydrogen. Energy is given out during the reaction, and if we measure how much energy we get from hydrogenation of trans-butene and compare it with the amount we get from cis-butene, we find that the cis-alkene give us about 2 kJ mol⁻¹ more. Cis-butene is higher in energy, and must therefore be less stable. We can represent this in the energy profile diagram on the right. The two red lines show the energies of the molecules, and the black arrows the amount of energy released when hydrogen is added.

This comparison of energy is most interesting when two compounds can interconvert. For example, as you saw in Chapter 7, rotation about the C–N bond of an amide is slow because delocalization of the N lone pair gives it some double-bond character. The C–N bond can rotate, but the rotation is slow and can be measured by NMR spectroscopy. We might expect to find two forms of an amide of the type R NH–COR: one with the two R groups trans to one another, and one with them cis. Depending on the size of R we should expect one form to be more stable than the other and we can represent this on an energy profile diagram showing the relationship between the two molecules in energy terms.
This time there is an axis along the bottom indicating the extent of rotation about the C–N bond. The two red lines show the energies of the molecules and the curved black line shows what must happen in energy terms as the two forms interconvert. Energy goes up as the C–N bond starts to rotate and reaches a maximum at point X when rotation by 90° has removed the conjugation (the nitrogen lone pair can’t delocalize into the C=O bond because it is perpendicular to the C=O π* orbital) before falling again as the conjugation is regained.

The relative energies of the two states will depend on the nature of R. The situation we have shown, with the cis arrangement being much less stable than the trans, would apply to large R groups. We can define an equilibrium constant \( K \) for this process. For large R groups, \( K \) will be very large:

\[
K = \frac{\text{[amide with R groups trans]}}{\text{[amide with R groups cis]}}
\]

At the other extreme is the case when both substituents on nitrogen are H. Then the two arrangements would have equal energies. The process which interconverts the structures is the same but there is now no difference between them. If you could measure an equilibrium constant, it would now be exactly \( K = 1 \).
In more general terms, amide rotation is a simple example of an equilibrium reaction. If we replace 'amount of C–N bond rotation' with 'reaction coordinate' we have a picture of a typical reaction in which reagents and products are in equilibrium.

**How the equilibrium constant varies with the difference in energy between reactants and products**

You saw that when the energies of the two forms of the amide were the same, the equilibrium constant for their interconversion must be $K = 1$. When one was higher in energy than the other, we just said that $K$ was 'large'. But we can be more specific. For any reaction in equilibrium, the equilibrium constant $K$ is related to the difference in energy between the starting materials and the products by the following equation:

$$
\Delta G = -RT \ln K
$$

where $\Delta G$ (the free energy of the reaction) is the difference in energy between the two states (in kJ mol$^{-1}$), $T$ is the temperature (in kelvin, not °C), and $R$ is a constant known as the gas constant and equal to 8.314 J K$^{-1}$ mol$^{-1}$.

This equation tells us that we can work out the equilibrium composition (how much of each component there is at equilibrium) provided we know the difference in energy between the products and reactants.

**An example: hydration of an aldehyde**

In Chapter 6 we showed you that water adds reversibly to the carbonyl group of an aldehyde: the aldehyde and the hydrate are in equilibrium. Here’s the example with isobutyraldehyde (2-methylpropanal). The equilibrium constant is the concentration of hydrate at equilibrium divided by the concentration of aldehyde, also at equilibrium.

$$
K = \frac{[\text{hydrate}]}{[\text{aldehyde}]} = \text{ca. 0.5}
$$

The concentrations of hydrate and aldehyde at equilibrium in water may be determined by measuring the UV absorption of known concentrations of aldehyde in water and comparing these with the absorptions in a solvent such as cyclohexane where no hydrate formation is possible. Such experiments reveal that the equilibrium constant for this reaction in water at 25 °C is approximately 0.5 so that there is about twice as much aldehyde as hydrate in the equilibrium mixture.

Using the equation above, we find that the corresponding value for $\Delta G$ is $-8.314 \times 298 \times \ln(0.5) = +1.7$ kJ mol$^{-1}$. In other words, the solution of the hydrate in water is 1.7 kJ mol$^{-1}$ higher in energy than the solution of the aldehyde in water. All this can be shown on an energy profile diagram.

**The sign of $\Delta G$ tells us whether products or reactants are favoured at equilibrium**

In the equilibrium above, the hydrate is higher in energy than the aldehyde: at equilibrium there is more aldehyde than hydrate, and the equilibrium constant is therefore less than 1. Whenever this is the case (i.e. the equilibrium lies to the side of the reactants, rather than the products).
products) $K$ will be less than 1. This means that its logarithm must be negative and, because $\Delta G = -RT \ln K$, $\Delta G$ must be positive. Conversely, for a reaction in which products are favoured over reactants, $K$ must be greater than 1, its logarithm will be positive, and hence $\Delta G$ must be negative. When $K$ is exactly 1, since $\ln 1 = 0$, $\Delta G$ will be zero.

- $\Delta G$ tells us about the position of equilibrium.
  - If $\Delta G$ for a reaction is negative, the products will be favoured at equilibrium.
  - If $\Delta G$ for a reaction is positive, the reactants will be favoured at equilibrium.
  - If $\Delta G$ for a reaction is zero, the equilibrium constant for the reaction will be 1.

A small change in $\Delta G$ makes a big difference in $K$

The tiny difference in energy between the hydrate and the aldehyde (1.7 kJ mol$^{-1}$) is small: the strength of a typical C–C bond is about 350 kJ mol$^{-1}$) gave an appreciable difference in the equilibrium composition. This is because of the logarithm term in the equation $\Delta G = -RT \ln K$: relatively small energy differences have a very large effect on $K$. The table below shows the equilibrium constants, $K$, that correspond to energy differences, $\Delta G$, between 0 and 50 kJ mol$^{-1}$. These are relatively small energy differences, but the equilibrium constants change by enormous amounts.

</table>

In a typical chemical reaction, ‘driving an equilibrium over to products’ might mean getting, say, 98% of the products and only 2% of starting materials. You can see in the table that this requires an equilibrium constant of just over 50 and an energy difference of only 10 kJ mol$^{-1}$. This small energy difference is quite enough—after all, a yield of 98% is rather good!

How to make the equilibrium favour the product you want

The direct formation of esters

The formation and hydrolysis of esters was discussed in Chapter 10 where we established that acid and ester are in equilibrium and that the equilibrium constant is about 1. Since the position of the equilibrium favours neither the starting materials nor the products, how can we manipulate the conditions of the reaction if we actually want to make 100% ester?

$$K = \frac{[\text{RCO}_2\text{Me}][\text{H}_2\text{O}]}{[\text{RCO}_2\text{H}][\text{MeOH}]} \approx \text{ca. } 1$$
The important point is that, at any one particular temperature, the equilibrium constant is just that—constant. This gives us a means of forcing the equilibrium to favour the products (or reactants) since the ratio between them must remain constant. Imagine what happens if we add more methanol to the reaction above. [MeOH] increases, but the overall value of $K$ has to stay the same. The only way this can happen is if more of the ester converts to the acid. Alternatively, imagine removing water from the equilibrium. [$H_2O$] goes down, so to bring $K$ back to the value of 1, the concentrations of acid and methanol are going to have to go down too, by converting themselves to ester and water.

$$K = \frac{[RCO_2Me][H_2O]}{[RCO_2H][MeOH]} = \text{ca. 1}$$

This is exactly how the equilibrium is manipulated in practice. One way to make esters in the laboratory is to use a large excess of the alcohol and remove water continually from the system as it is formed, for example by distilling it out. This means that in the equilibrium mixture there is a tiny quantity of water, lots of the ester, lots of the alcohol, and very little of the carboxylic acid; in other words, we have converted the carboxylic acid into the ester. We must still use an acid catalyst, but the acid must be anhydrous since we do not want any water present—commonly used acids are toluenesulfonic acid (tosic acid, TsOH), concentrated sulfuric acid ($H_2SO_4$), or gaseous HCl. The acid catalyst does not alter the position of the equilibrium; it simply speeds up the rate of the reaction, allowing equilibrium to be reached more quickly. This is an important point that we will come back to shortly.

**Typical method for making an ester**

Reflex the carboxylic acid with an excess of the alcohol (or the alcohol with an excess of the carboxylic acid) with about 3–5% of a mineral acid (usually HCl or $H_2SO_4$) as a catalyst and distil out the water that is formed in the reaction. For example, butanol was heated under reflux with a fourfold excess of acetic acid and a catalytic amount of concentrated $H_2SO_4$ to give butyl acetate in a yield of 70%.

$$\text{MeOH (4 equiv.)} + \text{HO} - \text{CO}_2\text{H} \rightarrow \text{MeO} - \text{CO}_2\text{H} \text{ (70% isolated yield)}$$

It may also help to distil out the water that is formed in the reaction: diethyl adipate (the diethyl ester of hexanedioic acid) can be made in toluene solution using a sixfold excess of ethanol, concentrated $H_2SO_4$ as catalyst, heating in toluene, and distilling out the water using a Dean Stark apparatus. You can tell from the yield that the equilibrium is very favourable.

$$\text{HO}_2\text{C} - \text{CO}_2\text{H} + \text{EtOH (6 equiv.)} \rightarrow \text{EtO}_2\text{C} - \text{CO}_2\text{Et} \text{ (96% isolated yield)}$$

In these cases the equilibrium is made more favourable by using an excess of reagents and/or removing one of the products. The equilibrium constant remains the same.
Typical method for hydrolysing an ester

Almost all methods for hydrolysing an ester in order to convert it back to an acid and an alcohol simply make use of excess water. Increasing [H₂O] forces more acid and alcohol to form to restore the equilibrium, and in favourable situations high yields of the acid and alcohol are formed.

Entropy is important in determining equilibrium constants

The equation we introduced on p. 243 tells us that an equilibrium favours whichever of the reactants or products has lower energy. But you might reasonably ask this question: why does it just favour the components with lower energy? Why do you get any of the higher energy ones at all? For the hydration on p. 243, for example, the hydrate is 1.7 kJ mol⁻¹ higher in energy than the starting aldehyde, so why does the aldehyde react at all? Surely the equilibrium would attain a lower energy state, not with just an excess of aldehyde over hydrate, but with no hydrate at all?

The answer is due to entropy, a measure of disorder. Even when there is a difference in energy between the starting materials and products in an equilibrium, you still get some of the less stable components. Put simply, having a mixture of components is favourable because a mixture has higher entropy than a pure compound, and equilibria tend to maximize overall entropy. This may be quite a new concept to you, so we will now work our way stepwise through these ideas.

Energy, enthalpy, and entropy: ΔG, ΔH, and ΔS

The equation in the margin just above tells us that the sign and magnitude of the energy ΔG are the only things that matter in deciding whether an equilibrium goes in one direction or another. If ΔG is negative the equilibrium will favour the products and if ΔG is large and negative the reaction can go to completion. The table on p. 244 tells us that it is enough for ΔG to be only about −10 kJ mol⁻¹ to get complete reaction. But we haven’t yet considered what ΔG actually corresponds to physically.

To do this we need to introduce our second equation. The free energy of a reaction, ΔG, is related to two other quantities, the enthalpy of reaction, ΔH, and the entropy of reaction, ΔS, by the equation:

$$ΔG = ΔH - TΔS$$

As before, T is the temperature of the reaction in kelvin. Enthalpy, H, is a measure of heat, and the change in enthalpy, ΔH, in a chemical reaction is the heat given out or taken up in that reaction. Reactions which give out heat are called exothermic, and have negative ΔH; reactions which take in heat are called endothermic and have positive ΔH. Since breaking bonds requires energy and making bonds liberates energy, the enthalpy change gives an indication of whether the products have more stable bonds than the starting materials or not.

Entropy, S, is a measure of the disorder in the system, so ΔS represents the entropy difference—the change in disorder—between the starting materials and the products. More disorder gives a positive ΔS; less disorder a negative ΔS.

So ΔG represents a combination of heat and disorder. But what does this mean for you as a chemist wanting to get a reaction to work the way you want it to? We know that for a favourable change (i.e. an equilibrium favouring products) ΔG must be negative—in fact the more negative the better, as this gives a larger equilibrium constant. Since ΔG = ΔH − TΔS, we get a large, negative ΔG most readily if:

1. ΔH is negative, i.e. the reaction is exothermic.

and

2. ΔS is positive (and hence −TΔS is negative), i.e. the reaction becomes more disordered.
Of course, we can still get a negative $\Delta G$ from an endothermic reaction (i.e. from a positive $\Delta H$) but only if the reaction products are more disordered than the starting materials; likewise a reaction which becomes more ordered as it proceeds can still be favourable, but only if it is exothermic to compensate for the loss of entropy.

Because of the factor $T$ multiplying the entropy term, both the equilibrium constant $K$ (which depends on $\Delta G$) and the relative importance of the two quantities ($\Delta H$ and $\Delta S$) will vary with temperature (entropy changes are more important at higher temperatures). We’ll now look at some examples to see how this works in practice.

**Enthalpy versus entropy—some examples**

Entropy dominates equilibrium constants in the difference between inter- and intramolecular reactions. In Chapter 6 we explained that hemiacetal formation is often an equilibrium, with neither starting materials nor products strongly favoured. The addition of ethanol to acetaldehyde shown below on the left, for example, has an equilibrium constant not far from 1. Overall, $\Delta G$ must therefore be approximately 0 (in fact it’s very slightly positive). The enthalpy change associated with the reaction is the result of the change in bonding: in this case, a C=O double bond becomes two C–O single bonds, and these two single bonds are marginally more stable than the C=O double bond, therefore $\Delta H$ is slightly negative. But working against this is the fact that every molecule of hemiacetal that forms consumes two molecules of starting material. Decreasing the number of molecules (and moving from a mixture of aldehyde and alcohol towards pure hemiacetal) leads to an increase in the order of the mixture—in other words a decrease in entropy. $\Delta S$ is negative, so the $-T\Delta S$ is positive, just about counterbalancing the small negative $\Delta H$, and giving a slightly positive $\Delta G$.

A mixture has more entropy than a pure substance because there are many more ways of arranging a mixture. Imagine lining up every molecule in a mole of substance and a mole of a 1:1 mixture. For the pure substance, each member of the line of molecules has to be the same. For the mixture, at every position in the line there is a choice of two alternatives, giving a huge number of possible arrangements.

The reaction on the right is different because it is an intramolecular reaction: the hydroxyl group and aldehyde lie in the same molecule. $\Delta H$ will have essentially the same value as in the intermolecular reaction on the left, but as the intramolecular reaction progresses, one molecule stays one molecule—there is consequently a much less significant decrease in entropy. Our $T\Delta S$ term no longer weighs against the negative $\Delta H$ term, making $\Delta G$ negative overall and allowing the equilibrium to lie to the right.

In Chapter 11 we showed you how acetals can be used as base-stable protective groups to prevent nucleophiles attacking carbonyl groups. The acetals we chose to use were cyclic compounds known as dioxolanes, for a very good reason: cyclic acetals are more resistant to hydrolysis than their acyclic counterparts. They are also easier to make—they form quite readily, even from ketones. Again, we have entropic factors to thank for their stability. For the formation of an acyclic acetal (below on the left), three molecules go in and two come out, but for a cyclic one, a cyclic acetal, two molecules go in (ketone plus diol) and two molecules come out (acetal plus water), so the usually unfavourable $\Delta S$ factor is no longer against us.
Overcoming entropy: orthoesters

There is a neat way of sidestepping the entropic problem associated with making acyclic acetals: we can use an orthoester as a source of alcohol. Orthoesters can be viewed as the ‘acetals of esters’, which are hydrolysed by water, when catalysed by acid, to an ordinary ester and two molecules of alcohol.

Here is the mechanism for the hydrolysis—you should be feeling quite familiar with this sort of thing by now.

Ketones or aldehydes undergo acetal exchange with orthoesters. The mechanism starts off as if the orthoester is going to hydrolyse but the alcohol released adds to the ketone and acetal formation begins. The water produced is taken out of the equilibrium by hydrolysis of the orthoester, and we get two molecules from two: entropy is no longer our enemy.

Equilibrium constants vary with temperature

We have said (p. 245) that the equilibrium constant is a constant only as long as the temperature does not change. We can work out exactly how the equilibrium constant varies with temperature by putting our two all-important equations $\Delta G = -RT \ln K$ and $\Delta G = \Delta H - T \Delta S$ together to make

$$-RT \ln K = \Delta H - T \Delta S$$

If we divide throughout by $-RT$ we have

$$\ln K = -\frac{\Delta H}{RT} + \frac{\Delta S}{R}$$

This equation separates the equilibrium constant $K$ into enthalpy and entropy terms, but it is the enthalpy term that determines how $K$ varies with temperature. Plotting $\ln K$ against $1/T$ would give us a straight line with slope $-\Delta H/R$ and intercept $\Delta S/R$. Since $T$ (the temperature in kelvin) is always positive, whether the slope is positive or negative depends on the sign of $\Delta H$: if $\Delta H$ is negative then, as temperature increases, $\ln K$ (and hence $K$) increases. In other words, if the reaction is exothermic (that is, gives out heat) then at higher temperatures the equilibrium constant will be smaller. For an endothermic reaction, as the temperature is increased, the equilibrium constant increases.

Some reactions are reversible on heating: cracking

Notice that the equation above also tells us that enthalpy becomes a less important contributor to the equilibrium constant as temperature increases, so the higher the temperature, the more important is the entropy term. This fact means that some reactions favour one side of the equilibrium at low temperature but the other at high temperature. Here is an example: the dimerization of cyclopentadiene. You will meet the mechanism of this reaction in Chapter 34, but for...
now we can just treat it as a simple dimerization reaction in which two C–C π bonds are replaced by two C–C σ bonds—enthalpically a very favourable process because σ bonds are stronger than π bonds. On standing at low temperature, cyclopentadiene converts to the dimer even though two monomer molecules have more entropy than one molecule of the dimer.

But on heating, the dimer breaks down to give monomeric cyclopentadiene: the equilibrium constant now favours the starting materials. As we predicted, because the reaction is exothermic, heating it makes it less favourable. You can also think of it in terms of our earlier equation \( \Delta G = \Delta H - T \Delta S \); at low temperature, the large negative \( \Delta H \) term dominates, and \( \Delta G \) is large and negative too. But as \( T \) increases, the positive \( \Delta S \) becomes more important, and eventually \( T \Delta S \) overtakes \( \Delta H \) and \( \Delta G \) becomes positive, and the reaction now favours starting materials.

If you want to use cyclopentadiene, you have to heat the dimer to ‘crack’ it (‘cracking’ is the term used for getting monomers from dimers or polymers). If you lazily leave the monomer overnight and plan to do your reaction tomorrow, you will return in the morning to find dimer.

This idea becomes even more pointed when we look at polymerization. Polyvinyl chloride is the familiar plastic PVC and is made by reaction of large numbers of monomeric vinyl chloride molecules. There is, of course, an enormous decrease in entropy in this reaction any polymerization will not occur above a certain temperature. Some polymers can be depolymerized at high temperatures and this can be the basis for recycling.

\[
\text{Cl} \quad \text{Cl} \quad \text{Cl} \quad \text{Cl} \quad \text{Cl} \\
\text{vinyl chloride} \\
\to \\
\text{Cl} \quad \text{Cl} \quad \text{Cl} \quad \text{Cl} \quad \text{Cl} \quad \text{Cl} \quad \text{Cl} \\
\text{PVC (polyvinylchloride)}
\]

- **Summary: Practical points from thermodynamic theory**
  - The free energy change \( \Delta G \) in a reaction is proportional to \( \ln K \) (that is, \( \Delta G = -RT \ln K \)).
  - \( \Delta G \) and \( K \) are made up of enthalpy and entropy terms (that is, \( \Delta G = \Delta H - T \Delta S \)).
  - The enthalpy change \( \Delta H \) is the difference in stability (bond strength) of the reagents and products.
  - The entropy change \( \Delta S \) is the difference between the disorder of the reagents and that of the products.
  - The enthalpy term alone determines how \( K \) varies with temperature.
  - The entropy change come to dominate control of equilibrium as temperature is raised.

---

**Le Châtelier’s principle**

You may well be familiar with a rule that helps to predict how a system at equilibrium responds to a change in external conditions—**Le Châtelier’s principle**. This says that if we disturb a system at equilibrium it will respond so as to minimize the effect of the disturbance. An example of a disturbance is adding more starting material to a reaction mixture at equilibrium. What happens? More product is formed to use up this extra material. This is a consequence of the equilibrium constant being, well..., constant and hardly needs anybody’s principle.

Another disturbance is heating. If a reaction under equilibrium is heated, how the equilibrium changes depends on whether the reaction is exothermic or endothermic. If it is exothermic (that is, gives out heat), Le Châtelier’s principle would predict that, since heat is consumed in the reverse reaction, more of the starting materials will be formed. Again no ‘principle’ is needed—this change occurs because the equilibrium constant is smaller at higher temperatures in an exothermic reaction. Avoid using principles and rules without understanding the science underneath them or you may find yourself playing with fire (which incidentally most definitely does not obey Le Châtelier’s principle, for very good reasons...).
Introducing kinetics: how to make reactions go faster and cleaner

Although in chemistry laboratories you will see lots of reactions being heated, very rarely will this be to alter the equilibrium position. This is because most reactions are not carried out reversibly and so the ratio of products to reactants is not an equilibrium ratio. The main reason chemists heat up reactions is simple—it speeds them up. The study of the rates of reactions, as opposed to their equilibrium states, is known as kinetics.

- Thermodynamics is concerned with equilibria; kinetics is concerned with rates.

How fast do reactions go? Activation energies

The combustion of the hydrocarbon shown below, the major component of petrol (gasoline) trivially known as ‘isooctane’, proceeds with \( \Delta G = \text{–1000 kJ mol}^{-1} \) at 298 K.

\[
\text{‘isooctane’ (l)} + \text{O}_2 (g) \quad \xrightleftharpoons{} \quad 8 \text{CO}_2 (g) + 9 \text{H}_2\text{O(l)}
\]

\( \Delta G = \text{–1000 kJ mol}^{-1} \)

The table on p. 244 shows that even a \( \Delta G \) of only \( \text{–50 kJ mol}^{-1} \) gives rise to a huge equilibrium constant: \( \text{–1000 kJ mol}^{-1} \) gives an equilibrium constant of \( 10^{175} \) (at 298 K), a number too vast to contemplate (there are ‘only’ about \( 10^{86} \) atoms in the observable universe). This value of \( \Delta G \) (or the corresponding value for the equilibrium constant) suggests that isooctane simply could not exist in the presence of oxygen. Yet we put it into the fuel tanks of our cars every day—clearly something is wrong.

Since isooctane can exist in an atmosphere of oxygen despite the fact that the equilibrium position really would be completely on the side of the combustion products, the only conclusion we can draw must be that a mixture of isooctane and oxygen cannot be at equilibrium. A small burst of energy is needed to reach equilibrium: in a car engine, the spark plug provides this energy and combustion occurs. Without this burst of energy, the petrol is stable and no combustion occurs (as you will ruefully be aware if you have ever tried to start a car with a flat battery).

The mixture of petrol and oxygen is said to be thermodynamically unstable with respect to the products of the reaction, CO\(_2\) and H\(_2\)O, but kinetically stable. We can be certain that they are thermodynamically unstable because even if the same small energy burst were applied to the products CO\(_2\) and H\(_2\)O, they would never convert back to petrol and oxygen.

Kinetically stable means that although the mixture could convert to a more stable set of products, it doesn’t do so because an energy barrier separates it from those products. An energy level diagram for a reaction such as the combustion of isooctane is shown below. The products are more stable (lower in energy) than the reactants, but to become the products, the reactants have to overcome a barrier to reaction. This barrier is called the activation energy and is usually given the symbol \( E_a \) or \( \Delta G^\ddagger \).
If a reaction cannot proceed until the reactants have sufficient energy to overcome the activation energy barrier, it is clear that, the smaller the barrier, the easier it will be for the reaction to proceed. Likewise, the more energy we give the starting materials in the form of temperature, the more likely it is that they will collide with sufficient combined energy to cross the activation energy barrier. Unlike equilibria, which can change in either direction, reaction rates always increase at higher temperatures.

A word of warning, however: heating is not all good for the chemist—not only does it speed up the reaction we want, it will also probably speed up lots of other reactions that we don’t want, including perhaps decomposition of the product! We shall see how we can get round this, but first we shall take a closer look at what determines how fast a reaction takes place.

**The route from reactants to products: the transition state**

The combustion of kinetically stable fuel releases lots of energy by a very complex mechanism. To understand how energy is involved in the progress of a reaction we will need to take a much more simple and familiar mechanism. The reduction of a ketone to an alcohol with sodium borohydride will do. You met this reaction in Chapters 5 and 6 and it should by now be a familiar part of your chemical vocabulary. An example is shown in the margin: in this particular case, the ketone is rather hindered by the adjacent tert-butyl group, and the reaction must be heated to form the product. Evidently, then, there is an activation barrier that must be overcome.

Let’s think about what that barrier might be. Although the final product is an alcohol, as you know well, the first step is transfer of a hydrogen atom from boron to the carbonyl group, as shown in the mechanism below. Overall, as shown in the energy profile diagram, the products of this step are more stable than the starting materials ($\Delta G$ is negative), but to get there the reaction has to pass through the activation energy barrier ($\Delta G^\ddagger$). This barrier—the highest energy point on the profile—must correspond to some structure (which we have shown in square brackets) in which the hydrogen atom is only partly transferred from B to C, and the carbonyl group is only partly broken. We call this structure—the highest energy form through which the molecules must pass to get from reactants to products—the **transition state**. It is often represented in square brackets, frequently with a double dagger symbol $\ddagger$ (to match the activation energy $\Delta G^\ddagger$).

Notice that the transition state has some features of the reactants and some features of the products. The B–H bond is partly broken, so we represent it as a dotted line, and the new H–C bond is partly formed, so likewise that is dotted too, as is the breaking C=O bond. The negative charge, which starts associated with B and ends on the oxygen atom, is shown in brackets in both locations, to indicate that it is shared between them. It takes energy to get to the transition state because the H has to move away from the B without significant compensation.
But once the transition state is passed, the formation of a stable C–H bond and the migration of a charge to electronegative oxygen means that stability is regained. A transition state is always unstable and can never be isolated: if the reaction proceeds just a little more forwards or backwards, the energy of the system is lower. Isolating a transition state would be like balancing a marble on top of a bowling ball.

**Transition state**

A transition state is a structure that represents an energy maximum on passing from reactants to products. It is not a real molecule in that it may have partially formed or broken bonds and may have more atoms or groups around the central atom than allowed by valence bond rules. It cannot be isolated because it is an energy maximum and any change in its structure leads to a more stable arrangement. A transition state is often shown by putting it in square brackets with a double-dagger superscript.

**Why some reactions are done at low temperature**

So far in this chapter you have seen that while heating a reaction can change the position of an equilibrium, the usual reason for heating a reaction is to speed it up by giving the reactants more energy to allow them to overcome the activation barrier. But as we said in the introduction, in a typical laboratory you will see many reactions being carried out at low temperatures. Why might a chemist want to slow a reaction down?

Well, often molecules can react in several different ways. A good reaction will have a lower activation energy than these alternatives. But often there are other unavoidable reactions waiting in the wings that will compete with the one that is wanted if the molecules have enough energy. The ideal situation is to give the starting materials enough energy to do the reaction we want, but not enough to do anything else: and that means keeping the reaction cold.

A famous example of a reaction which must be kept cold is the diazotization of anilines to make diazonium salts. The reaction involves treating the amine with nitrous acid (HONO) made from NaNO₂ and HCl. You need not think about the mechanism at this stage—you will meet it in Chapter 22—but the key point is that the product is a rather unstable but very useful diazonium salt. The diazotization takes place readily at room temperature, but unfortunately so does the decomposition of the product to give a phenol. By lowering the temperature, we supply insufficient energy for the phenol formation, but the diazotization still works just fine.
The use of organolithiums (which you saw in Chapter 9) typically involves low temperatures, often as low as –78 °C. Organolithiums are very reactive, and the addition or deprotonation reactions they undergo have activation energies sufficiently low that they proceed even at such temperatures. However, they do also have a tendency to attack some of the solvents which they dissolve best in, such as THF. If lithiations are attempted at higher temperatures, THF also reacts with s-BuLi to give the surprising by-products discussed in Chapter 35.

**Reaction intermediates**

Our mechanism for reduction of the ketone with borohydride is of course not yet complete: there is another step to follow—the protonation of the alkoxide by the ethanol solvent. We can add this step to our energy profile diagram.

Now the product of the first stage of the reaction is the starting material for the second, which follows on straightaway because the activation energy for the second reaction, the proton transfer, is smaller than for the first one. Notice that we have now labelled the middle set of structures, which includes the alkoxide ‘intermediate’. An intermediate is a staging post in a reaction pathway: it is stable for a finite (if short) period. Unlike a transition state it is a minimum rather than a maximum on the reaction energy profile, and therefore has a finite existence—an intermediate could, in principle, be isolated, and many have been (particularly at low temperature).

**Intermediates and transition states**

- A transition state represents an energy maximum—any small displacement leads to a more stable product. It can never be isolated.
- An intermediate is a molecule or ion that represents a localized energy minimum—an energy barrier must be overcome before the intermediate forms something more stable. An intermediate can in principle be isolated (although in practice its high energy can make this difficult).
Catalysis

You’ve met the idea in several places in this book (and probably elsewhere) that a catalyst increases the rate of a reaction. From what you have just read, it must therefore be the case that a catalyst lowers the activation energy for a reaction. It can do this in one or both of two ways: it can lower the energy of the transition state (as shown in the diagram on the left, or it can raise the energy of the starting materials.

To illustrate the point with a simple example, let’s take a reaction which simply does not work without a catalyst: the isomerization of butene. As you saw on p. 105, cis-but-2-ene is about 2 kJ mol⁻¹ higher in energy than trans-but-2-ene. This small energy difference would correspond to a 2.2:1, 70:30, trans:cis ratio of alkenes if they were in equilibrium. But it’s a big if: the activation energy needed to get from one to the other is of the order of 260 kJ mol⁻¹, which is practically unattainable. A quick calculation predicts that the half-life for the reaction would be approximately 10²⁵ years at room temperature, a time many orders of magnitude longer than the age of the universe. At 500 °C, however, the half-life is a more reasonable 4 hours, but unfortunately, when most alkenes are heated to these sorts of temperatures other unwanted reactions occur.

In order to interconvert the cis and trans isomers we must use a different strategy: catalysis. You will meet several ways of doing this in Chapter 27, but for the moment we will use just one: catalytic acid. As you saw in Chapter 5, alkenes are nucleophiles, and either isomer of but-2-ene can react with H⁺ from acid to form a transient species known as a carbocation. The activation energy for formation of the carbocation is much less than that for rotation about the C=C bond. The carbocation can now easily lose a proton again, to reform either cis- or trans-but-2-ene, regenerating the catalyst and allowing the interconversion to take place. Overall, the activation energy is much lower than in the uncatalysed reaction. We will come back to other examples of catalysis later in the chapter.

Solvents

The nature of the solvent used in reactions often has a profound effect on how the reaction proceeds. Sometimes, if the solvent is also a reagent, the choice is easy: it’s a good idea to carry out hydrolyses of esters in water and formations of esters in the appropriate alcohol because
the large concentration of the solvent drives the reaction towards the product, as explained on p. 208. Likewise, the solvent may also catalyse a reaction: ester formation from an acid chloride and an alcohol is often carried out in pyridine as a solvent because pyridine acts as a base catalyst of the reaction (p. 199).

On occasions, the choice of solvent is limited by simple features of the starting materials and products, such as their solubility or reactivity. Simple examples are cases where an inorganic salt is a reagent: ionic compounds are relatively insoluble in most organic solvents. Sodium bromide, for example, dissolves well in water, reasonably well in methanol, a little in ethanol, and hardly at all in most other organic solvents.

The insolubility of some salts in organic solvents can be used to drive an equilibrium in the direction required. For example, in the synthesis of this alkyl iodide from the alkyl bromide by reaction with sodium iodide, acetone is used as the solvent. Why? Well, sodium iodide is rather more soluble in acetone than is sodium bromide, so as sodium bromide is removed from the equilibrium mixture, more of the starting materials have to convert to the products to restore the equilibrium constant. You will meet more on this reaction in Chapter 15.

Water dissolves sodium bromide well because it solvates both cations and anions: electrostatic interactions with its δ− oxygen atoms can stabilize the positive sodium ions, while attraction to its δ+ hydrogen atoms can stabilize the negative bromide ion. Solvents which have polarized bonds like this are known as polar. Water and other alcohols are also called protic solvents because they have δ+ protons that can interact readily with anions.

Another group of polar solvents lack δ+ protons: these are the polar aprotic solvents, such as DMSO or DMF. Although they have a localized δ− at oxygen, which can solvate cations, they are much less good at solvating anions because their molecules do not have a localized accessible δ− region. In Chapter 10 (p. 213) you met a specific combination of t-BuOK and DMSO to help hydrolyse an amide. This is why DMSO is used here: it solvates the K⁺ cation, leaving the t-BuO⁻ unstabilized by solvation. It is desperate to become neutral by finding a proton. Metal alkoxides in DMSO are extremely basic, and when even sodium chloride is dissolved in DMSO the usually innocuous chloride ion becomes quite a powerful nucleophile, as you will see in Chapter 25.

A third group of solvents are not polar at all, but may still dissolve organic molecules quite well. These include hydrocarbons, chlorinated solvents (chloroform), and aromatic solvents (toluene, benzene).

The table below groups common solvents in classes with shared features, and also indicates their polarity. Polarity is measured in various ways—here we give the ‘dielectric constants’—but you do not need to remember the numbers. Learning the general position of a solvent in this sequence of polarity will, however, be a wise investment of your time.
By virtue of their ability or inability to solvate charged species, solvents can affect the course of reactions by stabilizing or destabilizing a transition state or an intermediate. Here’s a very simple example: the effect of solvent on one of the first ‘reactions’ in this chapter—the rotation about the C–N bond of an amide. The table in the margin shows the activation energy $\Delta G^\ddagger$ for C–N bond rotation in dimethylacetamide (DMA) in a range of solvents. You can immediately deduce that the rate of the rotation is fastest in the least polar solvent, cyclohexane, because the barrier is lowest. Why might this be?

To understand rates, we have to think about activation energies, in other words the difference in energy between the starting materials and the transition state. As you know, an amide in its ground state (in other words, its lowest energy state) is delocalized because of conjugation between the nitrogen’s lone pair and the carbonyl group. This delocalization leads to a degree of charge separation and polarization of the amide. But as the C–N bond rotates, the conjugation is broken because the molecule has to pass through a transition state in which the N lone pair is perpendicular to the $\pi$ system of the carbonyl group. The transition state is therefore less polar than the ground state.

Now, if we compare the effect on this rotation of a non-polar solvent and a polar solvent, this is what will happen. The polar ground state will be stabilized by the polar solvent, and so will be lower in energy, as you see on the right of the diagram below. But the less polar transition state will have about the same energy, whatever the polarity of the solvent. So, in a polar solvent, the amount of energy required to get from the ground state to the transition state (this is the activation energy, $E_a$ or $\Delta G^\ddagger$) is greater than in a non-polar solvent, and bond rotation is slower.
In Chapter 15 you will go on to meet a pair of mechanisms in which the polarity of the transition state is very different. You will now be prepared to expect some very significant solvent effects when such reactions take place.

- Solvents can affect the rate of a reaction by:
  - participating as a reagent
  - acting as a catalyst
  - dissolving the reagents
  - differentially stabilizing the ground state and transition state.

## Rate equations

We’ve pointed out that reactions go faster at higher temperature because the starting materials have more energy. But temperature is not the sole controller of rate. Two molecules might well collide with plenty of energy, but unless they are two molecules that can actually react, that energy will be lost as heat. Going back again to the reduction of p. 251 (a reminder in the margin), it’s obvious that only collisions between ketone (A) and borohydride (B) get us anywhere—there will be plenty of non-productive collisions between A and A or B and B. Obviously the chance of a collision between A and B is increased the more of each you have, and especially if you have lots of A and lots of B. In fact, the chance of a successful reaction is proportional to the product of the concentration of A and the concentration of B. We can express this in a simple rate equation:

\[
\text{rate of reaction} = k \times [A] \times [B]
\]

where the value \( k \) represents the rate constant for the reaction. The value of \( k \) is different for different reactions, and it also varies with temperature. The size of \( k \) also contains information about how likely it is that the molecules will collide with the right orientation. We call this analysis of the factors affecting the rate of the reactions the kinetics of the reaction.

There is of course a link between the activation energy of a reaction and its rate, and the connection between them is known as the Arrhenius equation, after the Swedish chemist Svante Arrhenius (1859–1927) who formulated it and won the Nobel Prize in 1903.

\[
k = A e^{-Ea/RT}
\]

where \( k \) is the rate constant for the reaction, \( R \) is the gas constant (see p. 243), \( T \) is the temperature (in kelvin), and \( A \) is a quantity known as the pre-exponential factor. Because of the minus sign in the exponential term, the larger the activation energy, \( E_a \), the slower the reaction but the higher the temperature, the faster the reaction.

As we discussed on p. 253, the reaction between borohydride and the ketone to make an alkoxide is only the first step of this reaction. Since ethanol likewise has to collide with the alkoxide for this second step to take place, you might very reasonably ask yourself why the rate of formation of the alcohol product does not also depend on \([\text{EtOH}]\): why is the rate equation not

\[
\text{rate of reaction} = k \times [\text{ketone}] \times [\text{borohydride}] \times [\text{EtOH}]
\]

The answer is hinted at in the energy profile diagram you saw on p. 253, which is reproduced below. The activation energy for the proton transfer step is lower than for the addition step, so it happens faster. It fact, it can happen fast whatever the concentration of ethanol, so ethanol does not appear in the rate equation. The overall rate of any reaction is determined only by what happens in the mechanistic step that is slowest, known as the rate-determining step or rate-limiting step. This is a general point about anything that happens in several
steps: if you want to empty a football stadium through a set of turnstiles, it is only the rate at which the turnstiles operate that limits the emptying speed—it doesn’t matter how quickly or slowly people walk away after they are through.

At several points in Chapters 6, 9, 10, and 11 we have said things like ‘don’t worry about the details of the proton transfers’ and now you know why: proton transfers between N and O atoms are fast, and other steps are almost always rate determining. It doesn’t really matter how you get a proton from one electronegative atom to another—in reality it will be flitting all over the place and any reasonable route is just as correct as any other.

- Proton transfers, particularly between O or N, are always fast and only rarely rate determining.

**Kinetics gives us an insight into the mechanism of a reaction**

In Chapters 10 and 11 you met some other multistep reactions with intermediates. Take this example: an alkoxide RO⁻ will react with an acid chloride to form an ester. If we measure how the rate of the formation of the ester varies with the concentration of the alkoxide and of the acid chloride, we discover a rate equation

\[
rate = k[\text{MeCOCl}][\text{RO}^-]
\]

Both the acid chloride and alkoxide must therefore be involved in the rate-determining step, which, as you know from Chapter 10, must be the formation of the tetrahedral intermediate. This intermediate is less stable than the starting materials, so the reaction energy profile takes the form shown below, with the highest transition state corresponding to the addition step.
The presence of two species in the rate equation confirms that the reaction is bimolecular (i.e. it involves two molecules), and we call such rate equations second order.

Numerous kinetic studies have confirmed that this mechanism, with a tetrahedral intermediate, is the normal pathway by which substitution reactions at carbonyl groups take place, as we explained in Chapter 10. You could draw a similar pathway, and a similar energy profile, for all of the reactions shown on p. 215, adjusting the energies of the starting materials, products, and intermediates appropriately, but all of them are second order, with rate-limiting attack on the carbonyl group.

However, there are occasional exceptions. These are not important enough for you to consider them likely when you write substitution mechanisms, but they do illustrate the fact that kinetics tells us about mechanism.

Here is one: when an acid chloride is heated with an alcohol in the absence of base, an ester forms. However, it turns out that under these conditions the rate equation is first order: it does not matter how much or how little alcohol is added, the rate depends only on the concentration of the acid chloride:

\[
\text{rate of reaction} = k[R^1\text{COCl}]
\]

Evidently, from the rate equation, no collision between the acid chloride and the alcohol is required for this reaction to go. The rate-determining step must be unimolecular. What actually happens is that the acid chloride decomposes by itself to give a reactive cation with the loss of the good leaving group Cl⁻.

Unusual unimolecular mechanism for ester formation

There are three steps in this reaction scheme, although the last is a trivial deprotonation. The energy barrier must be highest in the first step, which involves the acid chloride alone. The cation is an intermediate (although a short-lived one) with a real existence that reacts rapidly with the alcohol in a step that does not affect the rate of the reaction. The easiest way to picture this detail is in an energy profile diagram:
Notice that the products are again lower in energy than the starting materials, and although there are three transition states in this reaction, only the highest-energy transition state (the first one here) matters in determining the reaction rate. The reaction now passes through two intermediates (local minima). It is often the case that when intermediates are involved in a reaction, the highest-energy transition state is associated with the formation of the highest-energy intermediate.

**What does third-order kinetics mean?**

The first-order kinetics of this unusual substitution reaction is here to illustrate a point, but it should not distract you from the fact that most nucleophilic substitutions of carboxylic acid derivatives (the reactions you met in Chapter 10) are bimolecular reactions with rate-determining formation of the tetrahedral intermediate.

However, something different again happens when we come to reactions of amides. Because of the delocalization of the nitrogen lone pair into the carbonyl group, nucleophilic attack on the carbonyl group is very difficult. In addition, the leaving group (NH$_2^-$, with $pK_a$ of NH$_3$ about 35) is very bad indeed.
What happens as a consequence is that in the hydrolysis of amides the second step—the breakdown of the tetrahedral intermediate—becomes rate determining. But this offers the opportunity for base catalysis of this step. If a second hydroxide ion removes the proton from the tetrahedral intermediate, the loss of NH$_2$ from what is now a dianion is made easier, and a stable carboxylate ion is formed directly.

\[
\text{rate-determining step}
\]

Notice that in the first mechanism just one hydroxide ion is involved, whereas now two are involved: one is consumed to form product, but the second is in fact regenerated when the product NH$_2^-$ anion reacts with water—in other words the second hydroxide ion is a catalyst.

The rate equation for the amide hydrolysis reflects this involvement of two hydroxide ions: the rate depends on the square of the hydroxide ion concentration and it is third order. We’ll label the rate constant $k_3$ to emphasize this:

\[
\text{rate} = k_3[\text{MeCONH}_2] \times [\text{HO}^-]^2
\]

But you may be asking yourself where this third-order kinetics comes from, since the hydroxide ions are not actually involved in the rate-determining step. In fact, third-order kinetics hardly ever mean the real simultaneous termolecular collision of three molecules at once—such events are just too rare.

The rate-determining step here is actually unimolecular—the collapse of the dianion. So we expect

\[
\text{rate} = k[\text{dianion}]
\]

We don’t know the concentration of the dianion but we do know that it’s in equilibrium with the monoanion—we’ll call this equilibrium constant $K_2$:

\[
K_2 = \frac{[\text{dianion}]}{[\text{monoanion}][\text{HO}^-]}
\]

and so $[\text{dianion}] = K_2[\text{monoanion}][\text{HO}^-]$.

This sort of helps, but we still don’t know what $[\text{monoanion}]$ is, other than that it’s again in equilibrium, this time with the amide—we’ll call this equilibrium constant $K_1$:

\[
K_1 = \frac{[\text{monoanion}]}{[\text{amide}][\text{HO}^-]}
\]

and so $[\text{monoanion}] = K_1[\text{amide}][\text{HO}^-]$.

Substituting these values in the simple rate equation we discover that

\[
\text{rate} = k[\text{dianion}] \text{ becomes}
\]

\[
\text{rate} = kK_1K_2[\text{amide}][\text{HO}^-]^2
\]

The third-order kinetics result from two equilibria starting with the amide and involving two hydroxide ions, followed by a unimolecular rate-determining step, and the ‘third-order rate constant’ $k_3$ is actually a product of the two equilibrium constants and a first-order rate constant:

\[
k_3 = k \times K_1 \times K_2
\]

This often happens with reactions with late rate-determining steps: the rate constant can depend on the concentrations of any species involved before the rate-determining step (although not necessarily in that step itself) but never depends on species involved after the rate-determining step.
Just because a proposed mechanism gives a rate equation that fits the experimental data, it does not necessarily mean that it is the right mechanism; all it means is that it is consistent with the experimental facts so far, but there may be other mechanisms that also fit. It is then up to the experimenter to design cunning experiments to try to rule out other possibilities.

Mechanisms are given throughout this book—eventually you will learn to predict what mechanism to expect for a given type of reaction, but this is because earlier experimentalists have worked out the mechanisms by a study of kinetics and other methods.

**Catalysis in carbonyl substitution reactions**

The amide hydrolysis you have just met is much faster in base because base (in this case hydroxide) deprotonates the intermediate and makes it more reactive. The same is true for many other base-catalysed processes: often it is the nucleophile that is made more reactive by deprotonation to form an anion. For example, ester hydrolysis is faster at higher pH because the higher the pH the more hydroxide there is to act as a nucleophile.

We can plot this on a graph of rate vs. pH:

The rate equation at high pH is second order, as you expect, and depends on the concentration of hydroxide and the concentration of the ester. Notice, though, that below pH 7 the rate starts to increase again as the concentration of $[\text{H}^+]$ increases. This is because ester hydrolysis is also acid catalysed, as you saw in Chapter 10. At acidic pH, a new mechanism takes over in which protonation of the carbonyl group accelerates attack of weakly nucleophilic water.

The reaction is still bimolecular but the rate constant is different: we can represent the two processes by two rate equations, labelling the rate constants $k_a$ and $k_b$ with the suffixes ‘a’ for acid and ‘b’ for base to show more clearly what we mean:

rate of ester hydrolysis in acid (pH < 7) solution = $k_a[\text{MeCO}_2\text{R}][\text{H}_2\text{O}^+]$

rate of ester hydrolysis in basic (pH > 7) solution = $k_b[\text{MeCO}_2\text{R}][\text{HO}^-]$

This is typical acid–base catalysis, known as ‘specific acid–base catalysis’ because the specific acid and base involved are H⁺ (or $\text{H}_2\text{O}^+$) and OH⁻. The form of the pH dependence of the rate tells us that there is a choice of two mechanisms—the one that is faster is the one that is observed.

You met a reaction in Chapter 11 whose rate has a very different pH dependence: imine formation. To remind you, here is the mechanism again. We pointed out in Chapter 11 that
the reaction is acid catalysed because acid is needed to help water leave. But too much acid is a problem because it protonates the starting amine and slows the reaction down.

For these reasons, the pH–rate profile for imine formation looks like this: there is a maximum rate around pH 6, and either side the reaction goes more slowly.

The difference now is that at low pH, the rate-determining step changes from being the dehydration step (which can then go very fast because of the high concentration of acid) to being the addition step, which is slowed down by protonation of the amine. Whereas a reaction will always go by the fastest of the available mechanisms, it is also bound to go at the rate of the slowest step in that mechanism.

**Multistep reaction rates**

- The overall rate of a multistep reaction is decided by:
  - the fastest of the available mechanisms
  - the slowest of the possible rate-determining steps.

**Catalysis by weak bases**

In Chapter 10 we used pyridine as a catalyst in carbonyl substitution reactions, even though it is only a weak base. Catalysis by pyridine involves two mechanisms, and is discussed on p. 200. Acetate ion is another weak base which can catalyse the formation of esters from anhydrides:

The problem is, it is far too weak a base (acetic acid has a $pK_a$ of 5) to deprotonate the alcohol ($pK_a$ 15), so it can’t be forming alkoxide (in the way that hydroxide would for example). But what it can do is to remove the proton from the alcohol as the reaction occurs.
This type of catalysis, which is available to any base, not only strong bases, is called general base catalysis and will be discussed more in Chapter 39. It does not speed the reaction up very much but it does lower the energy of the transition state leading to the tetrahedral intermediate by avoiding the build-up of positive charge as the alcohol adds. The disadvantage of general base catalysis is that the first, rate-determining, step really is termolecular (unlike in the amide hydrolysis mechanism you met on p. 261). It is inherently unlikely that three molecules will collide with each other simultaneously. In this case, however, if ROH is the solvent, it will always be nearby in any collision so a termolecular step is just about acceptable.

Kinetic versus thermodynamic products

We started this chapter with a discussion of thermodynamics: the factors that govern equilibria. We then moved onto rates: the factors that determine the rate at which reactions proceed. Depending on the reaction, either may be more important, and in general:

- Reactions under thermodynamic control have outcomes that depend on the position of an equilibrium and therefore the relative stability of the possible products.
- Reactions under kinetic control have outcomes that depend on the rate at which the reaction proceeds, and therefore on the relative energies of the transition states leading to the alternative products.

Before we leave this chapter, we will introduce an example of a reaction where thermodynamic control and kinetic control lead to different outcomes—in other words, where the fastest reaction does not give the most stable possible product.

The reaction is one you have not yet met, but it is quite a simple one, and it follows an unsurprising mechanism. It is the reaction of an alkyne with hydrogen chloride in the presence of alumina (Al₂O₃). The reaction produces two geometrical isomers of a chloroalkene.

Alkynes, like alkenes, are nucleophiles, and so the mechanism involves first of all attack by the alkyne on HCl, followed by recombination of the vinyl cation, which is formed with the chloride anion.

The two alkenes are labelled E and Z. After about 2 hours the main product is the Z-alkene. However, this is not the case in the early stages of the reaction. The graph below shows how the proportions of the starting material and the two products change with time.

Points to note:

- When the alkyne concentration drops almost to zero (10 minutes), the only alkene that has been formed is the E-alkene.
• As time increases, the amount of $E$-alkene decreases as the amount of $Z$-alkene increases.
• Eventually, the proportions of $E$- and $Z$-alkene do not change.

Since it is the $Z$-alkene that dominates at equilibrium, this must be lower in energy than the $E$-alkene. Since we know the ratio of the products at equilibrium, we can work out the difference in energy between the two isomers:

\[
\text{ratio of } E:Z\text{-alkenes at equilibrium} = 1:35
\]

\[
K_{eq} = \frac{[Z]}{[E]} = 35
\]

\[
\Delta G = -RT \ln K = -8.314 \times 298 \times \ln(35) = -8.8 \text{ kJ mol}^{-1}
\]

that is, the $Z$-alkene is 8.8 kJ mol$^{-1}$ lower in energy than the $E$-alkene.

However, although the $Z$-alkene is more stable, the $E$-alkene is formed faster under these conditions: the route to the $E$-alkene must have a smaller activation energy barrier than trans addition. This is quite easy to understand: the intermediate cation has no double-bond geometry because the cationic $C$ is sp hybridized (linear). When chloride attacks, it prefers to attack from the side of the H atom rather than the (bigger) methyl group.

There must then be some mechanism by which the quickly formed $E$-alkene is converted into the more stable $Z$-alkene. The conditions are acidic, so the most likely mechanism is the acid-catalysed alkene isomerization you saw earlier in the chapter:

This information can be summarized on an energy profile diagram:
Initially, the alkyne is converted into the \( \text{E-alkene} \) via the intermediate linear cation. The activation energy for this step is labelled \( \Delta G^\dagger_1 \). The \( \text{E-alkene} \) can convert to the \( \text{Z-isomer} \) via an intermediate, with activation energy \( \Delta G^\dagger_2 \). Since \( \Delta G^\dagger_1 \) is smaller than \( \Delta G^\dagger_2 \), the \( \text{E-alkene} \) forms faster than it isomerizes, and all the alkyne is rapidly converted to the \( \text{E-alkene} \). But over the course of the reaction, the \( \text{E-alkene} \) slowly isomerizes to the \( \text{Z-alkene} \). An equilibrium is eventually reached that favours the \( \text{Z-alkene} \) because it is more stable (by 8.8 kJ mol\(^{-1} \), as we calculated earlier). Why doesn’t the \( \text{Z-alkene} \) form faster than the \( \text{E} \)? Well, as we suggested above, the transition state for its formation from the linear cation must be higher in energy than the transition state for formation of the \( \text{E-alkene} \), because of steric hindrance.

**Kinetic and thermodynamic products**

- The \( \text{E-alkene} \) is formed faster and is known as the kinetic product or the product of kinetic control.
- The \( \text{Z-alkene} \) is more stable and is known as the thermodynamic product or the product of thermodynamic control.

If we wanted to isolate the kinetic product, the \( \text{E-alkene} \), we would carry out the reaction at low temperature and not leave it long enough for equilibration. If, on the other hand, we want the thermodynamic product, the \( \text{Z-alkene} \), we would leave the reaction for longer at higher temperatures to make sure that the larger energy barrier yielding the most stable product can be overcome.

**Summary of mechanisms from Chapters 6–12**

In Chapter 5 we introduced basic arrow-drawing. A lot has happened since then and this is a good opportunity to pull some strands together. You may like to be reminded:

1. When molecules react together, one is the electrophile and one is the nucleophile.
2. Electrons flow from an electron-rich to an electron-poor centre.
3. Charge is conserved in each step of a reaction.

These three considerations will help you draw the mechanism of a reaction that you have not previously met.

**Types of reaction arrows**

1. Simple reaction arrows showing that a reaction goes from left to right or right to left.

   ![Reaction Arrows](image)

2. Equilibrium arrows showing the extent and direction of equilibrium.

   ![Equilibrium Arrows](image)

3. Delocalization or conjugation arrows showing two different ways to draw the same molecule. The two structures (‘canonical forms’ or ‘resonance structures’) must differ only in the position of electrons.

   ![Delocalization Arrows](image)
Using curly arrows

1. The curly arrow should show clearly where the electrons come from and where they go to.

\[
\text{is better than}
\]

2. If electrophilic attack on a π or σ bond leads to the bond being broken, the arrows should show clearly which atom bonds to the electrophile.

\[
\text{is better than}
\]

3. Reactions of the carbonyl group are dominated by the breaking of the π bond. If you use this arrow first on an unfamiliar reaction of a carbonyl compound, you will probably find a reasonable mechanism.

Shortcuts in drawing mechanisms

1. The most important is the double-headed arrow on the carbonyl group used during a substitution reaction.

\[
\text{is equivalent to:}
\]

2. The symbol ±H⁺ is shorthand for the gain and loss of a proton in the same step (usually involving N, O, or S: such steps are usually kinetically very fast).

\[
\text{is equivalent to:}
\]

Further reading

A physical chemistry text such as *Physical Chemistry*, 9th edn, by P. Atkins and J. de Paula, OUP, Oxford, 2011, will give you much more mathematical detail.

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at http://www.oxfordtextbooks.co.uk/orc/clayden2e/
The differences between carbon and proton NMR

We introduced nuclear magnetic resonance (NMR) in Chapter 3 as part of a three-pronged attack on the problem of determining molecular structure. We showed that mass spectrometry weighs the molecules, infrared spectroscopy tells us about functional groups, and $^{13}$C and $^1$H NMR tell us about the hydrocarbon skeleton. We concentrated on $^{13}$C NMR because it’s simpler, and we were forced to admit that we were leaving the details of the most important technique of all—proton ($^1$H) NMR—until a later chapter because it is more complicated than $^{13}$C NMR. This is that chapter and we must now tackle those complications. We hope you will see $^1$H NMR for the beautiful and powerful technique that it surely is. The difficulties are worth mastering for this is the chemist’s primary weapon in the battle to solve structures.

We will make use of $^1$H and $^{13}$C NMR evidence for structure throughout this book, and it is essential that you are familiar with the explanations in this chapter before you read further.

Proton NMR differs from $^{13}$C NMR in a number of ways.

- $^1$H is the major isotope of hydrogen (99.985% natural abundance), while $^{13}$C is only a minor isotope (1.1%).
- $^1$H NMR is quantitative: the area under the peak tells us the number of hydrogen nuclei, while $^{13}$C NMR may give strong or weak peaks from the same number of $^{13}$C nuclei.
- Protons interact magnetically (‘couple’) to reveal the connectivity of the structure, while $^{13}$C is too rare for coupling between $^{13}$C nuclei to be seen.

$^1$H NMR’ and ‘proton NMR’ are interchangeable terms. All nuclei contain protons of course, but chemists often use ‘proton’ specifically for the nucleus of a hydrogen atom, either as part of a molecule or in its ‘free’ form as $\text{H}^+$. This is how it will be used in this chapter.
• $^1$H NMR shifts give a more reliable indication of the local chemistry than that given by $^{13}$C spectra.

We shall examine each of these points in detail and build up a full understanding of proton NMR spectra.

Proton NMR spectra are recorded in the same way as $^{13}$C NMR spectra: radio waves are used to study the energy level differences of nuclei in a magnetic field, but this time they are $^1$H and not $^{13}$C nuclei. Hydrogen nuclei in a magnetic field have two energy levels: they can be aligned either with or against the applied magnetic field.

$^1$H and $^{13}$C spectra have many similarities: the scale runs from right to left and the zero point is given by the same reference compound, although it is the proton resonance of Me$_4$Si rather than the carbon resonance that defines the zero point. You will notice at once that the scale is much smaller, ranging over only about 10 ppm instead of the 200 ppm needed for carbon. This is because the variation in the chemical shift is a measure of the shielding of the nucleus by the electrons around it. There is inevitably less change possible in the distribution of two electrons around a hydrogen nucleus than in that of the eight valence electrons around a carbon nucleus. Here is the $^1$H NMR spectrum of acetic acid, which you first saw in Chapter 3.

Integration tells us the number of hydrogen atoms in each peak

You know from Chapter 3 that the position of a signal in an NMR spectrum tells us about its environment. In acetic acid the methyl group is next to the electron-withdrawing carbonyl group and so is slightly deshielded at about $\delta$ 2.0 ppm and the acidic proton itself, attached to O, is very deshielded at $\delta$ 11.2 ppm. The same factor that makes this proton acidic—the O–H bond is polarized towards oxygen—also makes it resonate at low field. So far things are much the same as in $^{13}$C NMR. Now for a difference. In $^1$H NMR the size of the peaks is also important: the area under the peaks is exactly proportional to the number of protons. Proton spectra are normally integrated, that is, the area under the peaks is computed and recorded as a line with steps corresponding to the area, like this.
Simply measuring the height of the steps with a ruler gives you the ratio of the numbers of protons represented by each peak. In many spectra this will be measured for you and reported as a number at the bottom of the spectrum. Knowing the atomic composition (from the mass spectrum) we also know the distribution of protons of various kinds. Here the heights are 6 mm and 18 mm, a ratio of about 1:3. The compound is C₂H₄O₂ so, since there are four H atoms altogether, the peaks must contain 1 × H and 3 × H, respectively.

In the spectrum of 1,4-dimethoxybenzene there are just two signals in the ratio of 3:2. This time the compound is C₈H₁₀O₂ so the true ratio must be 6:4. The positions of the two signals are exactly where you would expect them to be from our discussion of the regions of the NMR spectrum in Chapter 3: the 4H aromatic signal is in the left-hand half of the spectrum, between 5 and 10 ppm, where we expect to see protons attached to sp² C atoms, while the 6H signal is in the right-hand half of the spectrum, where we expect to see protons attached to sp³ C atoms.

In this next example it is easy to assign the spectrum simply by measuring the steps in the integral. There are two identical methyl groups (CMe₂) with six Hs, one methyl group by itself with three Hs, the OH proton (1 H), the CH₂ group next to the OH (two Hs), and finally the CH₃CH₂ group between the oxygen atoms in the ring (four Hs).

We will come back to the regions of the ¹H NMR spectrum in more detail in just a moment, but we introduced them in Chapter 3 on p. 60.
Before we go on, a note about the solvent peaks shown in brown in these spectra. Proton NMR spectra are generally recorded in solution in deuterochloroform (CDCl₃)—that is, chloroform (CHCl₃) with the ¹H replaced by ²H (deuterium). The proportionality of the size of the peak to the number of protons tells you why: if you ran a spectrum in CHCl₃, you would see a vast peak for all the solvent Hs because there would be much more solvent than the compound you wanted to look at. Using CDCl₃ cuts out all extraneous protons. ²H atoms have different nuclear properties and so don’t show up in the ¹H spectrum. Nonetheless, CDCl₃ is always unavoidably contaminated with a small amount of CHCl₃, giving rise to the small peak at 7.25 ppm. Spectra may equally well be recorded in other deuterated solvents such as water (D₂O), methanol (CD₃OD), or benzene (C₆D₆).

**Regions of the proton NMR spectrum**

All the H atoms in the last example were attached to sp³ carbons, so you will expect them to fall between 0 and 5 ppm. However, you can clearly see that H atoms that are nearer to oxygen are shifted downfield within the 0–5 ppm region, to larger δ values (here as far as 3.3 and 3.9 ppm). We can use this fact to build some more detail into our picture of the regions of the ¹H NMR spectrum.

These regions hold for protons attached to C: protons attached to O or N can come almost anywhere on the spectrum. Even for C–H signals the regions are approximate and overlap quite a lot. You should use the chart as a basic guide, and you should aim to learn these regions. But you will also need to build up a more detailed understanding of the factors affecting proton chemical shift. To help you achieve this understanding, we now need to examine the classes of proton in more detail and examine the reasons for their particular shifts. It is important that you grasp these reasons.

In this chapter you will see a lot of numbers—chemical shifts and differences in chemical shifts. We need these to show that the ideas behind ¹H NMR are securely based in fact. You do not need to learn these numbers. Comprehensive tables can be found at the end of Chapter 18, which we hope you will find useful for reference while you are solving problems.

**Protons on saturated carbon atoms**

**Chemical shifts are related to the electronegativity of substituents**

We shall start with protons on saturated carbon atoms. The top half of the diagram below shows how the protons in a methyl group are shifted more and more as the atom attached to them gets more electronegative.
When we are dealing with single atoms as substituents, these effects are straightforward and more or less additive. If we go on adding electronegative chlorine atoms to a carbon atom, electron density is progressively removed from it and the carbon nucleus and the hydrogen atoms attached to it are progressively deshielded. You can see this in the bottom half of the diagram above. Dichloromethane, CH₂Cl₂, and chloroform, CHCl₃, are commonly used as solvents and their shifts will become familiar to you if you look at a lot of spectra.

**Proton chemical shifts tell us about chemistry**

The truth is that shifts and electronegativity are not perfectly correlated. The key property is indeed electron withdrawal but it is the electron-withdrawing power of the whole substituent in comparison with the carbon and hydrogen atoms in the CH skeleton that matters. Methyl groups joined to the same element—nitrogen, say—may have very different shifts if the substituent is an amino group (CH₃–NH₂ has δH for the CH₃ group = 2.41 ppm) or a nitro group (CH₃–NO₂ has δH = 4.33 ppm). A nitro group is much more electron-withdrawing than an amino group.

What we need is a quick guide rather than some detailed correlations, and the simplest is this: all functional groups except very electron-withdrawing ones shift methyl groups from 1 ppm (where you find them if they are not attached to a functional group) downfield to about 2 ppm. Very electron-withdrawing groups shift methyl groups to about 3 ppm. This is the sort of thing it is worth learning.

---

### Estimating the chemical shift of a methyl group

</tbody>
</table>

Rather than trying to fit these data to some atomic property, even such a useful one as electronegativity, we should rather see these shifts as a useful measure of the electron-withdrawing power of the group in question. The NMR spectra are telling us about the chemistry. The largest shift you are likely to see for a methyl group is that caused by the nitro group, 3.43 ppm, at least twice the size of the shift for a carbonyl group. This gives us our first hint of some important chemistry: one nitro group is worth two carbonyl groups when it comes to electron-withdrawing power. You have already seen that electron withdrawal and acidity are related (Chapter 8) and in later chapters you will see that we can correlate the anion-stabilizing power of groups like carbonyl, nitro, and sulfone with proton NMR.

### Methyl groups give us information about the structure of molecules

It sounds rather unlikely that the humble methyl group could tell us much that is important about molecular structure—but just you wait. We shall look at four simple compounds and their NMR spectra—just the methyl groups, that is.

The first compound, the acid chloride in the margin, shows just one methyl signal containing nine Hs at δH 1.10. This tells us two things. All the protons in each methyl group are identical,
and all three methyl groups in the tertiary butyl ( t -butyl, or Me3C–) group are identical. This is because rotation about C–C single bonds, both about the CH3–C bond and about the (CH3)3C–C bond, is fast. Although at any one instant the hydrogen atoms in one methyl group, or the methyl groups in the t -butyl group, may differ, on average they are the same. The time-averaging process is fast rotation about a σ bond.

The second compound shows two 3H signals, one at 1.99 and one at 2.17 ppm. Unlike a C–C bond, the C=C double bond does not rotate at all and so the two methyl groups are different. One is on the same side of the alkene as (or ‘ cis to’) the –COCl group while the other is on the opposite side (or “trans”).

The next pair of compounds contain the CHO group. One is a simple aldehyde, the other an amide of formic acid: it is DMF, dimethylformamide. The first has two sorts of methyl group: a 3H signal at δH 1.81 for the SMe group and a 6H signal at δH 1.35 for the CMe2 group. The two methyl groups in the 6H signal are the same, again because of fast rotation about a C–C σ bond. The second compound also has two methyl signals, at 2.89 and 2.98 ppm, each 3H, and these are the two methyl groups on nitrogen. Restricted rotation about the N–CO bond must be making the two Me groups different. You will remember from Chapter 7 (p. 155) that the N–CO amide bond has considerable double-bond character because of conjugation: the lone pair electrons on nitrogen are delocalized into the carbonyl group.

Like double bonds, cage structures prevent bond rotation and can make the two protons of a CH2 group appear different. There are many flavouring compounds (terpenoids) from herbs that have structures like this. In the example here—myrtenal, from the myrtle bush—there is a four-membered ring bridged across a six-membered ring. The methyl groups on the other bridge are different because one is over the alkene while one is over the CH2. No rotation of any bonds within the cage is possible, so these methyl groups resonate at different frequencies (0.74 and 1.33 ppm). The same is true for the two H atoms of the CH2 group.

**CH and CH2 groups have higher chemical shift than CH3 groups**

Electronegative substituents have a similar effect on the protons of CH2 groups and CH groups, but with the added complication that CH3 groups have two other substituents and CH groups three. A simple CH2 (methylene) group resonates at 1.3 ppm, about 0.4 ppm further downfield than a comparable CH3 group (0.9 ppm), and a simple CH group resonates at 1.7 ppm, another 0.4 ppm downfield. Replacing each hydrogen atom in the CH3 group by a carbon atom causes a small downfield shift as carbon is slightly more electronegative (C 2.5; H 2.2) than hydrogen and therefore shields less effectively.

The benzyl group (PhCH2–) is very important in organic chemistry. It occurs naturally in the amino acid phenylalanine, which you met in Chapter 2. Phenylalanine has its CH2 signal at 3.0 ppm and is moved downfield from 1.3 ppm mostly by the benzene ring.

Amino acids are often ‘protected’ as the Cbz (carboxybenzyl) derivatives by reaction with an acid chloride (we’ll discuss this more in Chapter 23). Here is a simple example together
with the NMR spectrum of the product. Now the CH$_2$ group has gone further downfield to 5.1 ppm as it is next to both oxygen and phenyl.

![Chemical shifts of CH groups](image)

**Chemical shifts of CH groups**

A CH group in the middle of a carbon skeleton resonates at about 1.7 ppm—another 0.4 ppm downfield from a CH$_3$ group. It can have up to three substituents and these will cause further downfield shifts of about the same amount as we have already seen for CH$_3$ and CH$_2$ groups. Three examples from nature are nicotine, the methyl ester of lactic acid, and vitamin C. Nicotine, the compound in tobacco that causes the craving (although not the death, which is doled out instead by the carbon monoxide and tars in the smoke), has one hydrogen atom trapped between a simple tertiary amine and an aromatic ring at 3.24 ppm. The ester of lactic acid has a CH proton at 4.3 ppm. You could estimate this with reasonable accuracy using the guidelines in the two summary boxes on pp. 273 and 274. Take 1.7 (for the CH) and add 1.0 (for C=O) plus 2.0 (for OH) = 4.7 ppm—not far out. Vitamin C (ascorbic acid) has two CHs. One at 4.05 ppm is next to an OH group (estimate 1.7 + 2.0 for OH = 3.7 ppm) and one is next to a double bond and an oxygen atom at 4.52 ppm (estimate 1.7 + 1 for double bond + 2 for OH = 4.7 ppm). Again, not too bad for a rough estimate.

An interesting case is the amino acid phenylalanine whose CH$_2$ group we looked at a moment ago. It also has a CH group between the amino and the carboxylic acid groups. If we record the $^1$H NMR spectrum in D$_2$O, in either basic (NaOD) or acidic (DCl) solutions, we see a large shift of that CH group. In basic solution the CH resonates at 3.60 ppm and in acidic solution it resonates at 4.35 ppm. There is a double effect here: CO$_2$H and NH$_3^+$ are both more electron-withdrawing than CO$_2$ and NH$_3$ so both move the CH group downfield.

![Diagram of chemical shifts](image)
A simple guide to estimating chemical shifts

We suggest you start with a very simple (and therefore necessarily oversimplified) picture, which should be the basis for any further refinements. Start methyl groups at 0.9, methylenes (CH$_2$) at 1.3, and methines (CH) at 1.7 ppm. Any functional group is worth a 1 ppm downfield shift except oxygen and halogen which are worth 2 ppm. This diagram summarizes this approach.

![Chemical shift diagram](image)

The guide above is very rough and ready, but is easily remembered and you should aim to learn it. However, if you want to, you can make it slightly more accurate by adding further subdivisions and separating out the very electron-withdrawing groups (nitro, ester OCOR, fluoride), which shift by 3 ppm. This gives us the summary chart on this page, which we suggest you use as a reference. If you want even more detailed information, you can refer to the tables in Chapter 18 or better still the more comprehensive tables in any specialized text (see the Further reading section).

Summary chart of proton NMR shifts

![Summary chart of proton NMR shifts](image)
Answers deduced from this chart won’t be perfect but will give a good guide. Remember—these shifts are additive. Take a simple example, the ketoester below. There are just three signals and the integration alone distinguishes the two methyl groups from the CH₂ group. One methyl has been shifted from 0.9 ppm by about 1 ppm, the other by more than 2 ppm. The first must be next to C=O and the second next to oxygen. More precisely, 2.14 ppm is a shift of 1.24 ppm from our standard value (0.9 ppm) for a methyl group, about what we expect for a methyl ketone, while 3.61 ppm is a shift of 2.71 ppm, close to the expected 3.0 ppm for an ester joined through the oxygen atom. The CH₂ group is next to an ester and a ketone carbonyl group and so we expect it at 1.3 + 1.0 + 1.0 = 3.3 ppm, an accurate estimate, as it happens. We shall return to these estimates when we look at the spectra of unknown compounds.

The alkene region and the benzene region

In ¹³C NMR, alkene and benzene carbons came in the same region of the spectrum, but in the ¹H NMR spectrum the H atoms attached to arene C and alkene C atoms sort themselves into two groups. To illustrate this point, look at the ¹³C and ¹H chemical shifts of cyclohexene and benzene, shown in the margin. The two carbon signals are almost the same (1.3 ppm difference, < 1% of the total 200 ppm scale) but the proton signals are very different (1.6 ppm difference = 16% of the 10 ppm scale). There must be a fundamental reason for this.

The benzene ring current causes large shifts for aromatic protons

A simple alkene has an area of low electron density in the plane of the molecule because the π orbital has a node there, and the carbons and hydrogen nuclei lying in the plane gain no shielding from the π electrons.

The benzene ring looks similar at first sight, and the plane of the molecule is indeed a node for all the π orbitals. However, as we discussed in Chapter 7, benzene is aromatic—it has extra stability because the six π electrons fit into three very stable orbitals and are delocalized round the whole ring. The applied field sets up a ring current in these delocalized electrons that produces a local field rather like the field produced by the electrons around a nucleus. Inside the benzene ring the induced field opposes the applied field, but outside the ring it reinforces the applied field. The carbon atoms are in the ring itself and experience neither effect, but the hydrogens are outside the ring, feel a stronger applied field, and appear less shielded (i.e. more deshielded; larger chemical shift).
Cyclophanes and annulenes

You may think that it is rather pointless imagining what goes on inside an aromatic ring as we cannot have hydrogen atoms literally inside a benzene ring. However, we can get close. Compounds called cyclophanes have loops of saturated carbon atoms attached at both ends to the same benzene rings. You see here a structure for [7]-para-cyclophane, which has a string of seven CH₂ groups attached to the para positions of the same benzene ring. The four H atoms on the benzene ring itself appear as one signal at 7.07 ppm—a typical ring-current deshielded value for a benzene ring. The two CH₂ groups joined to the benzene ring (C1) are also deshielded by the ring current at 2.64 ppm. The next two sets of CH₂ groups on C2 and C3 are neither shielded nor deshielded at 1.0 ppm. But the middle CH₂ group in the chain (C4) must be pointing towards the ring in the middle of the π system and is heavily shielded by the ring current at –0.6 ppm.

With a larger aromatic ring it is possible actually to have hydrogen atoms inside the ring. Compounds are aromatic if they have 4n+2 delocalized electrons and this ring with nine double bonds, that is, 18 π electrons, is an example. The hydrogens outside the ring resonate in the aromatic region at rather low field (9.28 ppm) but the hydrogen atoms inside the ring resonate at an amazing –2.9 ppm, showing the strong shielding by the ring current. Such extended aromatic rings are called annulenes: you met them in Chapter 7.

Uneven electron distribution in aromatic rings

The 1H NMR spectrum of this simple aromatic amine has three peaks in the ratio 1:2:2, which must correspond to 3H:6H:6H. The 6.38 ppm signal clearly belongs to the protons round the benzene ring, but why are they at 6.38 and not at around 7.2 ppm? We must also distinguish the two methyl groups at 2.28 ppm from those at 2.89 ppm. The chart on p. 276 suggests that these should both be at about 2.4 ppm, close enough to 2.28 ppm but not to 2.89 ppm. The solution to both these puzzles is the distribution of electrons in the aromatic ring. Nitrogen feeds electrons into the π system, making it electron rich: the ring protons are more shielded and the nitrogen atom becomes positively charged and its methyl groups more deshielded. The peak at 2.89 ppm must belong to the NMe₂ group.

Other groups, such as simple alkyl groups, hardly perturb the aromatic system at all and it is quite common for all five protons in an alkyl benzene to appear as one signal instead of the three we might expect. Here is an example with some non-aromatic protons too: there is another on p. 275—the Cbz-protected amino acid.
The five protons on the aromatic ring all have the same chemical shift. Check that you can assign the rest. The OCH₃ group (green) is typical of a methyl ester (the chart on p. 276 suggests 3.9 ppm). One CH₂ group (yellow) is between two carbonyl groups (compare 3.35 ppm for the similar CH₂ group on p. 277). The other (red) is next to an ester and a benzene ring: we calculate 1.3 + 1.5 + 3.0 = 5.8 ppm for that—reasonably close to the observed 5.19 ppm. Notice how the Ph and the O together act to shift the Hs attached to this sp³ C downfield into what we usually expect to be the alkene region. Don’t interpret the regions on p. 272 too rigidly!

How electron donation and withdrawal change chemical shifts

We can get an idea of the effect of electron distribution by looking at a series of benzene rings with the same substituent in the 1 and 4 positions. This pattern makes all four hydrogens on the ring identical. Here are a few compounds listed in order of chemical shift: largest shift (lowest field; most deshielded) first. Conjugation is shown by the usual curly arrows, and inductive effects by a straight arrow by the side of the group. Only one hydrogen atom and one set of arrows are shown.

The largest shifts come from groups that withdraw electrons by conjugation. Nitro is the most powerful—this should not surprise you as we saw the same in non-aromatic compounds in both ¹³C and ¹H NMR spectra. Then come the carbonyl and nitrile group followed by groups showing simple inductive withdrawal. CF₃ is an important example of this kind of group—three fluorine atoms combine to exert a powerful effect.
In the middle of our sequence, around the position of benzene itself at 7.27 ppm, come the halogens, whose inductive electron withdrawal and lone pair donation are nearly balanced.

Alkyl groups are weak inductive donators, but the groups which give the most shielding—perhaps surprisingly—are those containing the electronegative atoms O and N. Despite being inductively electron withdrawing (the C–O and C–N \( \sigma \) bonds are polarized with \( \delta^+ C \)), on balance conjugation of their lone pairs with the ring (as you saw on p. 278) makes them net electron donors. They increase the shielding at the ring hydrogens. Amino groups are the best. Note that one nitrogen-based functional group (NO\(_2\)) is the best electron withdrawer while another (NH\(_2\)) is the best electron donor.

As far as the donors with lone pairs are concerned (the halogens plus O and N), two factors are important—the size of the lone pairs and the electronegativity of the element. If we look at the four halides at the top of this page the lone pairs are in 2p (F), 3p (Cl), 4p (Br), and 5p (I) orbitals. In all cases the orbitals on the benzene ring are 2p so the fluorine orbital is of the right size to interact well and the others too large. Even though fluorine is the most electronegative, it is still the best donor. The others don’t pull so much electron density away, but they can’t give so much back either.

If we compare the first row of the p block elements—F, OH, and NH\(_2\)—all have lone pairs in 2p orbitals so now electronegativity is the only variable. As you would expect, the most electronegative element, F, is now the weakest donor.

**Electron-rich and electron-deficient alkenes**

The same sort of thing happens with alkenes. We’ll concentrate on cyclohexene so as to make a good comparison with benzene. The six identical protons of benzene resonate at 7.27 ppm; the two identical alkene protons of cyclohexene resonate at 5.68 ppm. A conjugating and electron-withdrawing group such as a ketone removes electrons from the double bond as expected—but unequally. The proton nearer the C=O group is only slightly downfield from cyclohexene but the more distant one is over 1 ppm downfield. The curly arrows show the electron distribution, which we can deduce from the NMR spectrum.
Oxygen as a conjugating electron donor is even more dramatic. It shifts the proton next to it downfield by the inductive effect but pushes the more distant proton upfield a whole 1 ppm by donating electrons. The separation between the two protons is nearly 2 ppm.

For both types of substituent, the effects are more marked on the more distant (β) proton. If these shifts reflect the true electron distribution, we should be able to deduce something about the chemistry of the following three compounds. You might expect that nucleophiles will attack the electron-deficient site in the nitroalkene, while electrophiles will be attacked by the electron-rich sites in silyl enol ethers and enamines. These are all important reagents and do indeed react as we predict, as you will see in later chapters. Look at the difference—there are nearly 3 ppm between the shifts of the same proton on the nitro compound and the enamine!

Structural information from the alkene region

Alkene protons on different carbon atoms can obviously be different if the carbon atoms themselves are different and we have just seen examples of that. Alkene protons can also be different if they are on the same carbon atom. All that is necessary is that the substituents at the other end of the double bond should themselves be different. The silyl enol ether and the unsaturated ester below both fit into this category. The protons on the double bond must be different, because each is cis to a different group. We may not be able to assign which is which, but the difference alone tells us something. The third compound is an interesting case: the different shifts of the two protons on the ring prove that the N–Cl bond is at an angle to the C=\(\text{N}\) bond. If it were in line, the two hydrogens would be identical. The other side of the C=\(\text{N}\) bond is occupied by a lone pair and the nitrogen atom is trigonal (sp\(^3\) hybridized).

The aldehyde region: unsaturated carbon bonded to oxygen

The aldehyde proton is unique. It is directly attached to a carbonyl group—one of the most electron-withdrawing groups that exists—and is very deshielded, resonating with the largest shifts of any CH protons, in the 9–10 ppm region. The examples below are all compounds that we have met before. Two are just simple aldehydes—aromatic and aliphatic. The third is the solvent DMF. Its CHO proton is less deshielded than most—the amide delocalization that feeds electrons into the carbonyl group provides some extra shielding.
Conjugation with an oxygen lone pair has much the same effect—formate esters resonate at about 8 ppm—but conjugation with π bonds does not. The aromatic aldehyde above, simple conjugated aldehyde below, and myrtenal all have CHO protons in the normal region (9–10 ppm).

Non-aldehyde protons in the aldehyde region: pyridines

Two other types of protons resonate in the region around 9–10 ppm: some aromatic protons and some protons attached to heteroatoms like OH and NH. We will deal with NH and OH protons in the next section, but first we must look at some electron-deficient aromatic rings with distinctively large shifts.

Protons on double bonds, even very electron-deficient double bonds like those of nitroalkenes, hardly get into the aldehyde region. However, some benzene rings with very electron-withdrawing groups do manage it because of the extra downfield shift of the ring current, so look out for nitrobenzenes as they may have signals in the 8–9 ppm region.

More important molecules with signals in this region are the aromatic heterocycles such as pyridine, which you saw functioning as a base in Chapters 8 and 10. The NMR shifts clearly show that pyridine is aromatic: one proton is at 7.1 ppm, essentially the same as benzene, but the others are more downfield and one, at C2, is in the aldehyde region. This is not because pyridine is ‘more aromatic’ than benzene but because nitrogen is more electronegative than carbon. Position C2 is like an aldehyde—a proton attached to sp² C bearing a heteroatom—while C4 is electron deficient due to conjugation (the electron-negative nitrogen is electron withdrawing). Isoquinoline is a pyridine and a benzene ring fused together and has a proton even further downfield at 9.1 ppm—this is an imine proton that experiences the ring current of the benzene ring.

Protons on heteroatoms have more variable shifts than protons on carbon

Protons directly attached to O, N, or S (or any other heteroatom, but these are the most important) also have signals in the NMR spectrum. We have avoided them so far because the positions of these signals are less reliable and because they are affected by exchange.
In Chapter 2 you met the antioxidant BHT. Its proton NMR is very simple, consisting of just four lines with integrals 2, 1, 3, and 18. The chemical shifts of the tert-butyl group (brown), the methyl group on the benzene ring (orange), and the two identical aromatic protons (green) should cause you no surprise. What is left, the 1 H signal at 5.0 ppm (pink), must be the OH. Earlier on in this chapter we saw the spectrum of acetic acid, CH₃CO₂H, which showed an OH resonance at 11.2 ppm. Simple alcohols such as tert-butanol have OH signals in CDCl₃ (the usual NMR solvent) at around 2 ppm. Why such big differences?

This is a matter of acidity. The more acidic a proton is—that is, the more easily it can escape as H⁺ (this is the definition of acidity from Chapter 8)—the more the OH bond is polarized towards oxygen. The more the RO–H bond is polarized, the closer we are to free H⁺, which would have no shielding electrons at all, and so the further the proton goes downfield. The OH chemical shifts and the acidity of the OH group are—to a rough extent at least—related.

Thiols (RSH) behave in a similar way to alcohols but are not so deshielded, as you would expect from the smaller electronegativity of sulfur (phenols are all about 5.0 ppm, PhSH is at 3.41 ppm). Alkane thiols appear at about 2 ppm and arylthiols at about 4 ppm. Amines and amides show a big variation, as you would expect for the variety of functional groups involved, and are summarized below. Amides are slightly acidic, as you saw in Chapter 8, and amide protons resonate at quite low fields. Pyrroles are special—the aromaticity of the ring makes the NH proton unusually acidic—and they appear at about 10 ppm.

**Exchange of acidic protons is revealed in proton NMR spectra**

Compounds with very polar groups often dissolve best in water. NMR spectra are usually run in CDCl₃, but heavy water, D₂O, is an excellent NMR solvent. Here are some results in that medium.
Glycine is expected to exist as a zwitterion (Chapter 8, p. 167). It has a 2H signal (green) for the CH₂ between the two functional groups, which would do for either form. The 3H signal at 4.90 ppm (orange) might suggest the NH₃⁺ group, but wait a moment before making up your mind.

The aminothiol salt has the CMe₂ and CH₂ groups about where we would expect them (brown and green), but the SH and NH₃⁺ protons appear as one 4H signal.

The double salt of EDTA has several curious features. The two (green) CH₂ groups in the middle are fine, but the other four CH₂ (brown) groups all appear identical, as do all the protons on both the CO₂H and NH₃⁺ groups.

The best clue to why this is so comes from the strange coincidence of the chemical shifts of the OH, NH, and SH protons in these molecules. They are all the same within experimental error: 4.90 ppm for glycine, 4.80 ppm for the aminothiol, and 4.84 ppm for EDTA. In fact all correspond to the same species: HOD, or monodeuterated water. Exchange between XH (where X=O, N, or S) protons is extremely fast, and the solvent, D₂O, supplies a vast excess of exchangeable deuteriums. These immediately replace all the OH, NH, and SH protons in the molecules with D, forming HOD in the process. Recall that we do not see signals for deuterium atoms (that’s why deuterated solvents are used). They have their own spectra at a different frequency.
The same sort of exchange between OH or NH protons with each other or with traces of water in the sample means that the OH and NH peaks in most spectra in CDCl₃ are rather broader than the peaks for CH protons.

Two questions remain. First, can we tell whether glycine is a zwitterion in water or not? Not really: the spectra fit either or an equilibrium between both—other evidence leads us to expect the zwitterion in water. Second, why are all four CH₂CO groups in EDTA the same? This we can answer. As well as the equilibrium exchanging the CO₂H protons with the solvent, there will be an equally fast equilibrium exchanging protons between CO₂D and CO₂. This makes all four ‘arms’ of EDTA the same.

You should leave this section with an important chemical principle firmly established in your mind.

- Proton exchange between heteroatoms is fast
  Proton exchange between heteroatoms, particularly O, N, and S, is a very fast process in comparison with other chemical reactions, and often leads to averaged peaks in the ¹H NMR spectrum.

**Coupling in the proton NMR spectrum**

**Nearby hydrogen nuclei interact and give multiple peaks**

So far proton NMR has been not unlike carbon NMR on a smaller scale. However, we have yet to discuss the real strength of proton NMR, something more important than chemical shifts and something that allows us to look not just at individual atoms but also at the way the C–H skeleton is joined together. This is the result of the interaction between nearby protons, known as coupling.

An example we could have chosen in the last section is the nucleic acid component cytosine, which has exchanging NH₂ and NH protons giving a peak for HOD at 4.5 ppm. We didn’t choose this example because the other two peaks would have puzzled you. Instead of giving just one line for each proton, they give two lines each—doublets as you will learn to call them—and it is time to discuss the origin of this ‘coupling’.

- Cytosine is one of the four bases that, in combination with deoxyribose and phosphate, make up DNA. It is a member of the class of heterocycles called pyrimidines. We come back to the chemistry of DNA towards the end of this book, in Chapter 42.
You might have expected a spectrum like that of the heterocycle below, which like cytosine is also a pyrimidine. It too has exchanging NH$_2$ protons and two protons on the heterocyclic ring. But these two protons give the expected two lines instead of the four lines in the cytosine spectrum. It is easy to assign the spectrum: the green proton labelled H$^A$ is attached to an aldehyde-like C=N and so comes at lowest field. The red proton labelled H$^X$ is ortho to two electron-donating NH$_2$ groups and so comes at high field for an aromatic proton (p. 272). These protons do not couple with each other because they are too far apart. They are separated by five bonds whereas the ring protons in cytosine are separated by just three bonds.

\[ 2,6\text{-diaminopyrimidine} \]

Understanding this phenomenon is so important that we are going to explain it in three different ways—you choose which appeals to you most. Each method offers a different insight.

The diaminopyrimidine spectrum you have just seen has two single lines (singlets we shall call them from now on) because each proton, H$^A$ or H$^X$, can be aligned either with or against the applied magnetic field. The cytosine spectrum is different because each proton, say H$^A$, is near enough to experience the small magnetic field of the other proton H$^X$ as well as the field of the magnet itself. The diagram shows the result.

If each proton interacted only with the applied field we would get two singlets. But proton H$^A$ actually experiences two slightly different fields: the applied field plus the field of
HX or the applied field minus the field of HX. HX acts either to increase or decrease the field experienced by HA. The position of a resonance depends on the field experienced by the proton so these two situations give rise to two slightly different peaks—a doublet as we shall call it. And whatever happens to HA happens to HX as well, so the spectrum has two doublets, one for each proton. Each couples with the other. The field of a proton is a very small indeed in comparison with the field of the magnet and the separation between the lines of a doublet is very small. We shall discuss the size of the coupling later (pp. 294–300).

The second explanation takes into account the energy levels of the nucleus. In Chapter 4, when we discussed chemical bonds, we imagined electronic energy levels on neighbouring atoms interacting with each other and splitting to produce new molecular energy levels, some higher in energy and some lower in energy than the original atomic energy levels. When hydrogen nuclei are near each other in a molecule, the nuclear energy levels also interact and split to produce new energy levels. If a single hydrogen nucleus interacts with a magnetic field, we have the picture on p. 270 of this chapter: there are two energy levels as the nucleus can be aligned with or against the applied magnetic field, there is one energy jump possible, and there is a resonance at one frequency. This you have now seen many times and it can be summarized as shown below.

The spectrum of the pyrimidine on p. 286 shows exactly this situation: two protons well separated in the molecules and each behaving independently. Each has two energy levels, each gives a singlet, and there are two lines in the spectrum. But in cytosine, whose spectrum is shown on p. 285, the situation is different: each hydrogen atom has another hydrogen nucleus nearby and there are now four energy levels. Each nucleus HA and HX can be aligned with or against the applied field. There is one (lower) energy level where they are both aligned with the field and one (higher) level where they are both aligned against. In between there are two different energy levels in which one nucleus is aligned with the field and one against. Exciting H from alignment with to alignment against the applied field can be done in two slightly different ways, shown as A1 and A2 on the diagram. The result is two resonances very close together in the spectrum.
Please notice carefully that we cannot have this discussion about $H^4$ without discussing $H^X$ in the same way. If there are two slightly different energy jumps to excite $H^4$, there must also be two slightly different energy jumps to excite $H^X$. $A_1$, $A_2$, $X_1$, and $X_2$ are all different, but the difference between $A_1$ and $A_2$ is exactly the same as the difference between $X_1$ and $X_2$. Each proton now gives two lines (a doublet) in the NMR spectrum and the splitting of the two doublets is exactly the same. We describe this situation as coupling. We say ‘A and X are coupled’ or ‘X is coupled to A’ (and vice versa, of course). We shall be using this language from now on and so must you.

Now look back at the spectrum of cytosine at the beginning of this section. You can see the two doublets, one for each of the protons on the aromatic ring. Each is split by the same amount (this is easy to check with a ruler). The separation of the lines is the coupling constant and is called $J$. In this case $J = 4$ Hz. Why do we measure $J$ in hertz and not in ppm? We pointed out on p. 55 (Chapter 3) that we measure chemical shifts in ppm because we get the same number regardless of the rating of the NMR machine in MHz. We measure $J$ in Hz because we also get the same number regardless of the machine.

The spectra below show $^1H$ NMR spectra of the same compound run on two different NMR machines—one a 90 MHz spectrometer and one a 300 MHz spectrometer (these are at the lower and upper ends of the range of field strengths in common use). Notice that the peaks stay in the same place on the chemical shift scale (ppm) but the size of the coupling appears to change because 1 ppm is worth 90 Hz in the top spectrum but 300 Hz in the bottom.

Measuring coupling constants in hertz

To measure a coupling constant it is essential to know the rating of the NMR machine in MHz (megahertz). This is why you are told that each illustrated spectrum is, say, a ‘400 MHz $^1H$ NMR spectrum’. Couplings may be marked on the spectrum, electronically, but if not then to measure the coupling, measure the distance between the lines by ruler or dividers and use the horizontal scale to find out the separation in ppm. The conversion is then easy—to turn parts per million of megahertz into hertz you just leave out the million! So 1 ppm on a 300 MHz machine is 300 Hz. On a 500 MHz machine, a 10 Hz coupling is a splitting of 0.02 ppm.
When you change from one machine to another, say, from a 200 MHz to a 500 MHz NMR machine, chemical shifts (δ) stay the same in ppm and coupling constants (J) stay the same in Hz.

Now for the third way to describe coupling. If you look again at what the spectrum would be like without interaction between HA and HX you will see the pattern on the right, with the chemical shift of each proton clearly obvious.

But you don’t see this because each proton couples with the other and splits its signal by an equal amount either side of the true chemical shift. The true spectrum has a pair of doublets each split by an identical amount. Note that no line appears at the true chemical shift, but it is easy to measure the chemical shift by taking the midpoint of the doublet.

So this spectrum would be described as 7.5 (1H, d, J = 4 Hz, HA) and 5.8 (1H, d, J = 4 Hz, HX). The main number gives the chemical shift in ppm and then, in brackets, comes the integration as the number of Hs, the shape of the signal (here ‘d’ for doublet), the size of coupling constants in Hz, and the assignment, usually related to a diagram. The integration refers to the combined area under both peaks in the doublet. If the doublet is exactly symmetrical, each peak integrates to half a proton. The combined signal, however complicated, integrates to the right number of protons.

We have described these protons as A and X with a purpose in mind. A spectrum of two equal doublets is called an AX spectrum. A is always the proton you are discussing and X is another proton with a different chemical shift. The alphabet is used as a ruler: nearby protons (on the chemical shift scale—not necessarily nearby in the structure!) are called B, C, etc. and distant ones are called X, Y, etc. You will see the reason for this soon.

If there are more protons involved, the splitting process continues. Here is the NMR spectrum of a famous perfumery compound supposed to have the smell of ‘green leaf lilac’. The compound is an acetal with five nearly identical aromatic protons at the normal benzene position (7.2–7.3 ppm) and six protons on two identical OMe groups.

It is the remaining three protons that interest us. They appear as a 2H doublet at 2.9 ppm and a 1H triplet at 4.6 ppm. In NMR talk, triplet means three equally spaced lines in the ratio 1:2:1. The triplet arises from the three possible states of the two identical protons in the CH₂ group.

If one proton HA interacts with two protons HX, it can experience protons HX in three different possible states. Both protons HX can be aligned with the magnet or both against. These states will increase or decrease the applied field just as before. But if one proton HX is aligned with and one against the applied field, there is no net change to the field experienced by HA. There are two arrangements for this (see diagram overleaf). We’ll therefore see a signal of double intensity for HA at the correct chemical shift, one signal at higher field and one at lower field. In other words, a 1:2:1 triplet.
We could look at this result by our other methods too. There is one way in which both nuclei can be aligned with and one way in which both can be aligned against the applied field, but two ways in which they can be aligned one with and one against. Proton $\text{HA}$ interacts with each of these states. The result is a 1:2:1 triplet.

Using our third way of seeing coupling to see how the triplet arises, we can just make the peaks split in successive stages:
If there are more protons involved, we continue to get more complex systems, but the intensities can all be deduced simply from Pascal’s triangle, which gives the coefficients in a binomial expansion. If you are unfamiliar with this simple device, here it is.

You can read off from the triangle what pattern you may expect when a proton is coupled to \( n \) equivalent neighbours. There are always \( n + 1 \) peaks with the intensities shown by the triangle. So far, you’ve seen 1:1 doublets (line 2 of the triangle) from coupling to 1 proton, and 1:2:1 triplets (line 3) from coupling to 2. You will often meet ethyl groups (\( \text{CH}_3\text{CH}_2X \)), where the \( \text{CH}_2 \) group couples to three identical protons and appears as a 1:3:3:1 quartet and the methyl group as a 1:2:1 triplet. In isopropyl groups, (\( \text{CH}_3 \))\( _2\text{CH}X \), the methyl groups appear as a 6H doublet and the \( \text{CH} \) group as a septuplet.

Here is a simple example: the four-membered cyclic ether oxetane. Its NMR spectrum has a 4H triplet for the two identical \( \text{CH}_2 \) groups next to oxygen and a 2H quintet for the \( \text{CH}_2 \) in the middle. Each proton \( H^X \) ‘sees’ four identical neighbours (\( H^0 \)) and is split equally by them all to give a 1:4:6:4:1 quintet. Each proton \( H^A \) ‘sees’ two identical neighbours \( H^X \) and is split into a 1:2:1 triplet. The combined integral of all the lines in the quintet together is 2 and of all the lines in the triplet is 4.
A slightly more complicated example is the diethyl acetal below. It has a simple AX pair of doublets for the two protons on the ‘backbone’ (red and green) and a typical ethyl group (2H quartet and 3H triplet). An ethyl group is attached to only one substituent through its CH₂ group, so the chemical shift of that CH₂ group tells us what it is joined to. Here the peak at 3.76 ppm can only be an OEt group. There are, of course, two identical CH₂ groups in this molecule.

In all of these molecules, a proton may have had several neighbours, but all those neighbours have been the same. And therefore all the coupling constants have been the same. What happens when coupling constants differ? Chrysanthemic acid, the structural core of the insecticides produced by pyrethrum flowers, gives an example of the simplest situation—where a proton has two different neighbours.
Chrysanthemic acid has a carboxylic acid, an alkene, and two methyl groups on the three-membered ring. Proton $H^A$ has two neighbours, $H^X$ and $H^M$. The coupling constant to $H^X$ is 8 Hz, and that to $H^M$ is 5.5 Hz. We can construct the splitting pattern as shown on the right.

The result is four lines of equal intensity called a **double doublet** or sometimes a **doublet of doublets**), abbreviation dd. The smaller coupling constant can be read off from the separation between lines 1 and 2 or between lines 3 and 4, while the larger coupling constant is between lines 1 and 3 or between lines 2 and 4. The separation between the middle two lines is not a coupling constant. You could view a double doublet as an imperfect triplet where the second coupling is too small to bring the central lines together: alternatively, look at a triplet as a special case of a double doublet where the two couplings are identical and the two middle lines coincide.

### Coupling is a through-bond effect

Do neighbouring nuclei interact through space or through the electrons in the bonds? We know that coupling is in fact a ‘through-bond effect’ because of the way coupling constants vary with the shape of the molecule. The most important case occurs when the protons are at either end of a double bond. If the two hydrogens are **cis**, the coupling constant $J$ is typically about 10 Hz, but if they are **trans**, $J$ is much larger, usually 15–18 Hz. These two chloro acids are good examples.

If coupling were through space, the nearer **cis** hydrogens would have the larger $J$. In fact, coupling occurs **through the bonds** and the more perfect parallel alignment of the bonds in the **trans** compound provides better communication and a larger $J$.

Coupling is at least as helpful as chemical shift in assigning spectra. When we said (p. 280) that the protons on cyclohexenone had the chemical shifts shown, how did we know? It was coupling that told us the answer. The proton next to the carbonyl group ($H^2$ in the diagram) has one neighbour ($H^3$) and appears as a doublet with $J = 11$ Hz, just right for a proton on a double bond with a **cis** neighbour. The proton $H^3$ itself appears as a double triplet. Inside each triplet the separation of the lines is 4 Hz and the two triplets are 11 Hz apart.

The coupling of $H^3$ is as complex as you have seen yet, but it can be represented diagrammatically by the same approach we have taken before.
As coupling gets more and more complicated it can be hard to interpret the results, but if you know what you are looking for things do become easier. Here is the example of heptan-2-one. The green protons next to the carbonyl group are a 2H triplet (coupled to the two red protons) with $J \approx 7$ Hz. The red protons themselves are next to four protons, and although these four protons are not identical the coupling constants are about the same: the red protons therefore appear as a 2H quintet, with a coupling constant also of 7 Hz. The brown signal is more complicated: we might call it a ‘4H multiplet’ but in fact we know what it must be: the signals for the four brown protons on carbons 5 and 6 overlap, and must be made up of a 2H quintet (protons on C5) and a 2H sextet (protons on C6). We can see the coupling of the protons on C6 with the terminal methyl group because the methyl group (orange) is a 3H triplet (also with a 7 Hz coupling constant).

Coupling constants depend on three factors

The coupling constants in cyclohexenone were different, but all the coupling constants in heptanone are about the same—around 7 Hz. Why?

- Factors affecting coupling constants
  - Through-bond distance between the protons.
  - Angle between the two C–H bonds.
  - Electronegative substituents.
The coupling constants we have seen so far have all been between hydrogen atoms on neighbouring carbon atoms—in other words, the coupling is through three bonds (H–C–C–H) and is designated $^3J_{HH}$. These coupling constants $^3J_{HH}$ are usually about 7 Hz in an open-chain, freely rotating system such as we have in heptanone. The C–H bonds vary little in length but in cyclohexenone the C–C bond is a double bond, significantly shorter than a single bond. Couplings ($^3J_{HH}$) across double bonds are usually larger than 7 Hz (11 Hz in cyclohexenone). $^3J_{HH}$ couplings are called vicinal couplings because the protons concerned are on neighbouring carbon atoms.

Something else is different too: in an open-chain system we have a time average of all rotational conformations (we will look at this in the next chapter). But across a double bond there is no rotation and the angle between the two C–H bonds is fixed: they are always in the same plane. In the plane of the alkene, the C–H bonds are either at 60° (cis) or 180° (trans) to each other. Coupling constants in benzene rings are slightly less than those across cis alkenes because the bond is longer (bond order 1.5 rather than 2).

In naphthalenes, there are unequal bond lengths around the two rings. The bond between the two rings is the shortest, and the lengths of the others are shown. Coupling across the shorter bond (8 Hz) is significantly stronger than coupling across the longer bond (6.5 Hz).

The effect of the third factor, electronegativity, is easily seen in the comparison between ordinary alkenes and alkenes with alkoxy substituents, known as enol ethers. We are going to compare two pairs of compounds with a cis or a trans double bond. One pair has a phenyl group at one end of the alkene and the other has an OPh group. For either pair, the trans coupling is larger than the cis, as you would now expect. But if you compare the two pairs, the enol ethers have much smaller coupling constants. The trans coupling for the enol ethers is only just larger than the cis coupling for the alkenes. The electronegative oxygen atom is withdrawing electrons from the C–H bond in the enol ethers and weakening communication through the bonds.

**Long-range coupling**

When the through-bond distance gets longer than three bonds, coupling is not usually seen. To put it another way, four-bond coupling $^4J_{HH}$ is usually zero. However, it is seen in some special cases, the most important being meta coupling in aromatic rings and allylic coupling in alkenes. In both, the orbitals between the two hydrogen atoms can line up in a zig-zag
fashion to maximize interaction. This arrangement looks rather like a letter ‘W’ and this sort of coupling is called W-coupling. Even with this advantage, values of $J_{HH}$ are usually small, about 1–3 Hz.

*Meta* coupling is very common when there is *ortho* coupling as well, but here is an example where there is no *ortho* coupling because none of the aromatic protons have immediate neighbours—the only coupling is *meta* coupling. There are two identical HAs, which have one *meta* neighbour and appear as a 2H doublet. Proton HX between the two MeO groups has two identical *meta* neighbours and so appears as a 1H triplet. The coupling is small ($J \sim 2.5$ Hz).

![Diagram showing W-coupling and meta-coupling.](image)

We have already seen a molecule with allylic coupling. We discussed in some detail why cyclohexenone has a double triplet for H3. But it also has a less obvious double triplet for H2. The triplet coupling is less obvious since $J$ is small (about 2 Hz) because it is $4J_{HH}$—allylic coupling to the CH2 group at C4. Here is a diagram of the coupling, which you would be able to spot in an expansion of the cyclohexenone spectrum on p. 293.

![Diagram showing allylic coupling.](image)

**Coupling between similar protons**

Identical protons do not couple with each other. The three protons in a methyl group may couple to some other protons, but *never* couple with each other. They are an $A_3$ system. Identical neighbours do not couple either. Turn back to p. 271 and you’ll see that even though each of the four protons on the *para*-disubstituted benzenes has one neighbour, they appear as one singlet because every proton is identical to its neighbour.

We have also seen how two different protons forming an AX system give two separate doublets. Now we need to see what happens to protons in between these two extremes. What happens to two similar neighbours? As two protons get closer and closer together, do the two doublets you see in the AX system suddenly collapse to the singlet of the $A_3$ system? You have probably guessed that they do not. The transition is gradual. Suppose we have two different neighbours on an aromatic ring. The spectra below show what we see. These are all 1,4-disubstituted benzene rings with different groups at the 1 and 4 positions.
You'll notice that when the two doublets are far apart, as in the first spectrum, they look like normal doublets. But as they get closer together the doublets get more and more distorted, until finally they are identical and collapse to a 4H singlet.

The critical factor in the shape of the peak is how the difference between the chemical shifts of the two protons (Δδ) compares with the size of the coupling constant (J) for the machine in question. If Δδ is much larger than J there is no distortion: if, say, Δδ is 2 ppm at 500 MHz (= 1000 Hz) and the coupling constant is a normal 7 Hz, then this condition is fulfilled and we have an AX spectrum of two 1:1 doublets. As Δδ approaches J in size, so the inner lines of the two doublets increase and the outer lines decrease until, when Δδ is zero, the outer lines vanish away altogether and we are left with the two superimposed inner lines—a singlet or an A2 spectrum. You can see this progression in the diagram on the right.
We call the last stages, where the distortion is great but the protons are still different, an AB spectrum because you cannot really talk about H¹ without also talking about H². The two inner lines may be closer than the gap between the doublets or the four lines may all be equally spaced. Two versions of an AB spectrum are shown in the diagram—there are many more variations.

It is a generally useful tip that a distorted doublet ‘points’ towards the protons with which it is coupled.

Or, to put it another way, the AB system is ‘roofed’ with the usual arrangement of low walls and a high middle to the roof. Look out for doublets (or any other coupled signals) of this kind.

We shall end this section with a final example illustrating para-disubstituted benzenes and roofing as well as an ABX system and an isopropyl group. The aromatic ring protons form a pair of distorted doublets (2H each), showing that the compound is a para-disubstituted benzene. Then the alkene protons form the AB part of an ABX spectrum. They are coupled to each other with a large (trans) J = 16 Hz and one is also coupled to another distant proton. The large doublets are distorted (AB) but the small doublets within the right-hand half of the AB system are equal in height. The distant proton X is part of an i-Pr group and is coupled to H⁶ and the six identical methyl protons. Both Js are nearly the same so it is split by seven protons and is an octuplet. It looks like a sextuplet because the intensity ratios of the lines in an octuplet would be 1:7:21:35:35:21:7:1 (from Pascal’s triangle) and it is hardly surprising that the outside lines disappear.

**Coupling can occur between protons on the same carbon atom**

We have seen cases where protons on the same carbon atom are different: compounds with an alkene unsubstituted at one end. If these protons are different (and they are certainly near to each other), then they should couple. They do, but in this case the coupling constant is usually very small. Here is the spectrum of an example you met on p. 281.
The small 1.4 Hz coupling is a $^2J_{HH}$ coupling between two protons on the same carbon that are different because there is no rotation about the double bond. $^2J_{HH}$ coupling is called geminal coupling.

This means that a monosubstituted alkene (a vinyl group) will have characteristic signals for each of the three protons on the double bond. Here is the example of ethyl acrylate (ethyl acrylate, a monomer for the formation of acrylic polymers). The spectrum looks rather complex at first, but it is easy to sort out using the coupling constants.

The largest $J$ (16 Hz) is obviously between the orange and green protons (trans coupling), the medium $J$ (10 Hz) is between the orange and red (cis coupling), and the small $J$ (4 Hz) must be between the red and green (geminal). This assigns all the protons: red, 5.60 ppm; green, 6.40 ppm; orange, 6.11 ppm. Assignments based on coupling are more reliable than those based on chemical shift alone.

**Coupling constants in a vinyl group**

- $^2J_{HH}$ cis coupling large 10–13 Hz
- $^2J_{HH}$ trans coupling v. large 14–18 Hz
- $^2J_{HH}$ geminal coupling v. small 0–2 Hz
Ethyl vinyl ether is a reagent used for the protection of alcohols. All its coupling constants are smaller than is usual for an alkene because of the electronegativity of the oxygen atom, which is now joined directly to the double bond. It is still a simple matter to assign the protons of the vinyl group because couplings of 13, 7, and 2 Hz must be trans, cis, and geminal, respectively. In addition, the orange H is on a carbon atom next to oxygen and so goes downfield while the red and green protons have extra shielding from the conjugation of the oxygen lone pairs (see p. 281).

Geminal coupling on saturated carbons can be seen only if the hydrogens of a CH₂ group are different. The bridging CH₂ group of myrtenal (p. 274) provides an example. The coupling constant for the protons on the bridge, $J_{AB}$, is 9 Hz. Geminal coupling constants in a saturated system can be much larger (typically 10–16 Hz) than in an unsaturated one.

**Typical coupling constants**

- **geminal** $J_{HH}$
  - saturated
    - $R$: 10–16 Hz
  - unsaturated
    - $R$: 0–3 Hz

- **vicinal** $J_{HH}$
  - saturated
    - $R$: 6–8 Hz
  - unsaturated trans
    - $R$: 14–18 Hz
  - unsaturated cis
    - $R$: 10–12 Hz
To conclude

You have now met, in Chapter 3 and this chapter, all of the most important spectroscopic techniques available for working out the structure of organic molecules. We hope you can now appreciate why proton NMR is by far the most powerful of these techniques, and we hope you will be referring back to this chapter as you read the rest of the book. We shall talk about proton NMR a lot, and specifically we will come back to it in detail in Chapter 18, where we will look at using all of the spectroscopic techniques in combination, and in Chapter 31, when we look at what NMR can tell us about the shape of molecules.

Further reading

A reminder: you will find it an advantage to have one of the short books on spectroscopic analysis to hand as they give explanations, comprehensive tables of data, and problems. We recommend Spectroscopic Methods in Organic Chemistry by D. H. Williams and Ian Fleming, McGraw-Hill, London, 6th edn, 2007.

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at http://www.oxfordtextbooks.co.uk/orc/clayden2e/
Some compounds can exist as a pair of mirror-image forms

One of the very first reactions you met, back in Chapter 6, was between an aldehyde and cyanide. The product was a compound containing a nitrile group and a hydroxyl group.

\[
\begin{align*}
\text{RCHO} + \text{CN}^- & \rightarrow \text{RCNHO} \\
\end{align*}
\]

How many products are formed in this reaction? Well, the straightforward answer is one—there's only one aldehyde, only one cyanide ion, and only one reasonable way in which they can react. But this analysis is not quite correct. One point that we ignored when we first talked about this reaction, because it was irrelevant at that time, is that the carbonyl group of the aldehyde has two faces. The cyanide ion could attack either from the front face or the back face, giving, in each case, a distinct product.

Interactive results of cyanide addition to carbonyls

- The bold wedges represent bonds coming towards you, out of the paper, and the cross-hatched bonds represent bonds going away from you, into the paper.

Interactive support. The icon in the margin indicates that accompanying interactive resources are provided online to help your understanding: just type www.chemtube3d.com/clayden/123 into your browser, replacing 123 with the number of the page where you see the icon. For pages linking to more than one resource, type 123-1, 123-2 etc. (replacing 123 with the page number) for access to successive links.
As we explained in Chapter 6 (pp. 125–7), the cyanide attacks the \( \pi^* \) orbital of the aldehyde more or less at right angles to the plane of the molecule as it forms a new bond with the old \( p \) orbital on C. This translates into ‘front’ and ‘back’ on a diagram on paper. Compare the diagram on the left with the others to make sure this is clear.

Are these two products different? If we lay them side by side and try to arrange them so that they look identical, we find that we can’t—you can verify this by making models of the two structures. The structures are non-superimposable—so they are not identical. In fact, they are mirror images of each other: if we reflected one of the structures, A, in a mirror, we would get a structure that is identical with B.

We call two structures that are not identical but are mirror images of each other (like these two) **enantiomers**. Structures that are not superimposable on their mirror image, and can therefore exist as two enantiomers, are called **chiral**. In this reaction, the cyanide ions are just as likely to attack the ‘front’ face of the aldehyde as they are the ‘back’ face, so we get a 50:50 mixture of the two enantiomers.

Now consider another similar reaction—the addition of cyanide to acetone.

Again an adduct (a cyanohydrin) is formed. You might imagine that attacking the front or the back face of the acetone molecule could again give two structures, C and D.

However, this time rotating one to match the other shows that they are superimposable and therefore identical.
Make sure that you are clear about this: C and D are identical molecules, while A and B are mirror images of each other. Reflection in a mirror makes no difference to C or D; they are superimposable on their own mirror images and therefore cannot exist as two enantiomers. Structures that are superimposable on their mirror images are called achiral.

** Achiral structures are superimposable on their mirror images.**

### Chiral molecules have no plane of symmetry

What is the essential difference between these two compounds that means one is superimposable on its mirror image and one is not? The answer is symmetry. Acetone cyanohydrin has a plane of symmetry running through the molecule. This plane cuts the central carbon and the OH and CN groups in half, and has one methyl group on each side. All planar molecules (such as our simple aldehyde) cannot be chiral as the plane of the molecule must be a plane of symmetry. Cyclic molecules may have a plane of symmetry passing through two atoms of the ring, as in the cyclohexanone below. The plane passes through both atoms of the carbonyl group and bisects the methyl group as well as the hydrogen atom (not shown) on the same carbon atom. The bicyclic acetal looks more complicated but a plane of symmetry passes between the two oxygen atoms and the two ring-junction carbon atoms while bisecting the two methyl groups. None of these molecules is chiral.

On the other hand, the aldehyde cyanohydrin has no plane of symmetry: the plane of the paper has OH on one side and CN on the other while the plane at right angles to the paper has H on one side and RCH₂ on the other. This compound has no plane of symmetry (has asymmetry) and has two enantiomers.

**Planes of symmetry and chirality**

- Any structure that has no plane of symmetry is chiral and can exist as two mirror-image forms (enantiomers).
- Any structure with a plane of symmetry is not chiral and cannot exist as two enantiomers.

By ‘structure’, we don’t just mean chemical structure: the same rules apply to everyday objects. Some examples from among more familiar objects in the world around us should help make these ideas clear. Look around you and find a chiral object—a pair of scissors, a screw (but not the screwdriver), a car, and anything with writing on it, like this page. Look again for achiral objects with planes of symmetry—a plain mug, saucepan, chair, most simple manufactured objects without writing on them. The most significant chiral object near you is the hand you write with.
Gloves, hands, and socks

Most gloves exist in pairs of non-identical mirror-image forms: only a left glove fits a left hand and only a right glove fits a right hand. This property of gloves and of the hands inside them gives us the word ‘chiral’—cheir is Greek for ‘hand’. Hands and gloves are chiral; they have no plane of symmetry, and a left glove is not superimposable on its mirror image (a right glove). Feet are chiral too, as are shoes. But socks (usually!) are not. Although we all sometimes have problems finding two socks of a matching colour, once you’ve found them, you never have to worry about which sock goes on which foot because socks are achiral. A pair of socks is manufactured as two identical objects, each of which has a mirror plane.

The ancient Egyptians had less care for the chirality of hands and their paintings often show people, even Pharaohs, with two left hands or two right hands—they just didn’t seem to notice.

Tennis racquets and golf clubs

If you are left-handed and want to play golf, you either have to play in a right-handed manner or get hold of a set of left-handed golf clubs. Golf clubs are clearly therefore chiral; they can exist as either of two enantiomers. You can tell this just by looking at a golf club. It has no plane of symmetry, so it must be chiral. But left-handed tennis players have no problem using the same racquets as right-handed tennis players and tennis players of either chirality sometimes swap the racquet from hand to hand. Look at a tennis racquet: it has a plane of symmetry (indeed, usually two), so it’s achiral. It can’t exist as two mirror-image forms.
To summarize

- A structure with a plane of symmetry is achiral and superimposable on its mirror image and cannot exist as two enantiomers.
- A structure without a plane of symmetry is chiral and not superimposable on its mirror image and can exist as two enantiomers.

**Stereogenic centres**

Back to chemistry, and the product from the reaction of an aldehyde with cyanide. We explained above that this compound, being chiral, can exist as two enantiomers. Enantiomers are clearly isomers; they consist of the same parts joined together in a different way. In particular, enantiomers are a type of isomer called stereoisomers because the isomers differ not in the connectivity of the atoms, but only in the overall shape of the molecule.

**Stereoisomers and constitutional isomers**

Isomers are compounds that contain the same atoms bonded together in different ways. If the connectivity of the atoms in the two isomers is different, they are constitutional isomers. If the connectivity of the atoms in the two isomers is the same, they are stereoisomers. Enantiomers are stereoisomers, and so are $E$ and $Z$ double bonds. We shall meet other types of stereoisomers shortly.

We should also introduce you briefly to another pair of concepts here, which you will meet again in more detail in Chapter 16: configuration and conformation. Two stereoisomers really are different molecules: they cannot be interconverted without breaking a bond somewhere. We therefore say that they have different configurations. But any molecule can exist in a number of conformations: two conformations differ only in the temporary way the molecule happens to arrange itself, and can easily be interconverted just by rotating around bonds. Humans all have the same configuration: two arms joined to the shoulders. We may have different conformations: arms folded, arms raised, pointing, waving, etc.

**Configuration and conformation**

- Changing the configuration of a molecule always means that bonds are broken.
- A different configuration is a different molecule.
- Changing the conformation of a molecule means rotating about bonds, but not breaking them.
- Conformations of a molecule are readily interconvertible, and are all the same molecule.

The aldehyde cyanohydrin is chiral because it does not have a plane of symmetry. In fact, it cannot have a plane of symmetry because it contains a tetrahedral carbon atom carrying four different groups: OH, CN, RCH$_2$, and H. Such a carbon atom is known as a stereogenic or chiral centre. The product of cyanide and acetone is not chiral; it has a plane of symmetry and no chiral centre because two of the groups on the central carbon atom are the same.
If a molecule contains one carbon atom carrying four different groups it will not have a plane of symmetry and must therefore be chiral. A carbon atom carrying four different groups is a stereogenic or chiral centre.

We saw how the two enantiomers of the aldehyde cyanohydrin arose by attack of cyanide on the two faces of the carbonyl group of the aldehyde. We said that there was nothing to favour one face over the other, so the enantiomers must be formed in equal quantities. A mixture of equal quantities of a pair of enantiomers is called a racemic mixture.

A racemic mixture is a mixture of two enantiomers in equal proportions. This principle is very important. If all the starting materials and reagents in a reaction are achiral and the products are chiral they will be formed as a racemic mixture of two enantiomers.

Here are some more reactions you have come across that make chiral products from achiral starting materials. In each case, the principle must hold—equal amounts of the two enantiomers (racemic mixtures) are formed.

Many chiral molecules are present in nature as single enantiomers. Let’s turn to some simple, but chiral, molecules—the natural amino acids. All amino acids have a carbon carrying an amino group, a carboxyl group, a hydrogen atom, and the R group, which varies from amino acid to amino acid. So unless R = H (this is the case for glycine), amino acids always contain a chiral centre and lack a plane of symmetry.

It is possible to make amino acids quite straightforwardly in the laboratory. The scheme below shows a synthesis of alanine, for example. It is a version of the Strecker synthesis you met in Chapter 11.
Alanine made in this way must be racemic because the starting material and all reagents are achiral. However, if we isolate alanine from a natural source—by hydrolysing vegetable protein, for example—we find that this is not the case. Natural alanine is solely one enantiomer, the one drawn in the margin. Samples of chiral compounds that contain only one enantiomer are called enantiomerically pure. We know that ‘natural’ alanine contains only this enantiomer from X-ray crystal structures.

Enantiomeric alanine

In fact, nature does sometimes (but very rarely) use the other enantiomer of alanine, for example in the construction of bacterial cell walls. Some antibiotics (such as vancomycin) owe their selectivity to the way they can recognize these ‘unnatural’ alanine components and destroy the cell wall that contains them.

Chiral and enantiomerically pure

Before we go further, we should just mention one common point of confusion. Any compound whose molecules do not have a plane of symmetry is chiral. Any sample of a chiral compound that contains molecules all of the same enantiomer is enantiomerically pure. All alanine is chiral (the structure has no plane of symmetry) but laboratory-produced alanine is racemic (a 50:50 mixture of enantiomers) whereas naturally isolated alanine is enantiomerically pure.

● ‘Chiral’ does not mean ‘enantiomerically pure’.

Most of the molecules we find in nature are chiral—a complicated molecule is much more likely not to have a plane of symmetry than to have one. Nearly all of these chiral molecules in living systems are found not as racemic mixtures, but as single enantiomers. This fact has profound implications, for example in the chemistry of drug design, and we will come back to it later.

R and S can be used to describe the configuration of a chiral centre

Before going on to talk about single enantiomers of chiral molecules in more detail, we need to explain how chemists describe which enantiomer they’re talking about. We can, of course, just draw a diagram, showing which groups go into the plane of the paper and which groups come out of the plane of the paper. This is best for complicated molecules. Alternatively, we can use the following set of rules to assign a letter, R or S, to describe the configuration of groups at a chiral centre in the molecule.

1. Assign a priority number (1–4) to each substituent at the chiral centre. Atoms with higher atomic numbers get higher priority.

Alanine’s chiral centre carries one N atom (atomic number 7), two C atoms (atomic number 6), and one H atom (atomic number 1). So, we assign priority 1 to the NH₂ group, because N has the highest atomic number. Priorities 2 and 3 will be assigned to the CO₂H and the CH₂ groups, and priority 4 to the hydrogen atom; but we need a way of deciding which of CO₂H and CH₂ takes priority over the other. If two (or more) of the atoms attached to the chiral centre are identical, then we assign priorities to these two by assessing the atoms attached to those atoms. In this case, one of the carbon atoms carries oxygen atoms (atomic number 8) and one carries only hydrogen atoms (atomic number 1). So CO₂H is higher priority that CH₂; in other words, CO₂H gets priority 2 and CH₂ priority 3.

2. Arrange the molecule so that the lowest priority substituent is pointing away from you. In our example, naturally extracted alanine, H is priority 4, so we need to look at the molecule with the H atom pointing into the paper, like this.
3. Mentally move from substituent priority 1 to 2 to 3. If you are moving in a clockwise manner, assign the label R to the chiral centre; if you are moving in an anticlockwise manner, assign the label S to the chiral centre.

A good way of visualizing this is to imagine turning a steering wheel in the direction of the numbering. If you are turning your car to the right, you have R; if you are turning to the left you have S. For our molecule of natural alanine, if we move from NH₂ (1) to CO₂H (2) to CH₃ (3) we’re going anticlockwise (turning to the left), so we call this enantiomer (S)-alanine.

You can try working the other way, from the configurational label to the structure. Take lactic acid as an example. Lactic acid is produced by bacterial action on milk; it’s also produced in your muscles when they have to work with an insufficient supply of oxygen, such as during bursts of vigorous exercise. Lactic acid produced by fermentation is often racemic, although certain species of bacteria produce solely (R)-lactic acid. On the other hand, lactic acid produced by anaerobic respiration in muscles has the S configuration.

As a brief exercise, try drawing the three-dimensional structure of (R)-lactic acid. You may find this easier if you draw both enantiomers first and then assign a label to each. You should have drawn:

![Image of (R)-lactic acid structure]

Remember that, if we had made lactic acid in the laboratory from simple achiral starting materials, we would have got a racemic mixture of (R)- and (S)-lactic acid. Reactions in living systems can produce enantiomerically pure compounds because they make use of enzymes, themselves enantiomerically pure compounds of (S)-amino acids.

Is there a chemical difference between two enantiomers?

The short answer is no.* Take (S)-alanine (in other words, alanine extracted from plants) and (R)-alanine (the enantiomer found in bacterial cell walls) as examples. They have identical NMR spectra, identical IR spectra, and identical physical properties with a single important exception. If you shine plane-polarized light through a solution of (S)-alanine, you will find that the light is rotated to the right. A solution of (R)-alanine rotates plane-polarized light to the left and by the same amount. Racemic alanine doesn’t rotate such light at all.

The rotation of plane-polarized light is known as optical activity

Observation of the rotation of plane-polarized light is known as polarimetry; it is a straightforward way of finding out if a sample is racemic or if it contains more of one enantiomer than the other. Polarimetric measurements are carried out in a polarimeter, which has a single-wavelength (monochromatic) light source with a plane-polarizing filter, a sample holder, where a cell containing a solution of the substance under examination can be placed, and a detector with a read-out that indicates by how much the light is rotated. Rotation to the right is given a positive value, rotation to the left a negative one.

![Diagram of polarimeter setup]

* Plane-polarized light can be considered as a beam of light in which all of the light waves have their direction of vibration aligned parallel. It is produced by shining light through a polarizing filter.

* The longer answer is more involved, and we go into it in more detail in Chapter 41.
The angle through which a sample of a compound (usually a solution) rotates plane-polarized light depends on a number of factors, the most important ones being the path length (how far the light has to pass through the solution), concentration, temperature, solvent, and wavelength. Typically, optical rotations are measured at 20 °C in a solvent such as ethanol or chloroform, and the light used is from a sodium lamp, with a wavelength of 589 nm.

The observed angle through which the light is rotated is given the symbol \( \alpha \). By dividing this value by the path length \( \cdot \) (in dm) and the concentration \( c \) (in g cm\(^{-3}\)) we get a value, \([\alpha]\), which is specific to the compound in question. Indeed, \([\alpha]\) is known as the compound’s **specific rotation**. The choice of units is eccentric and arbitrary but is universal so we must live with it.

\[
[\alpha] = \frac{\alpha}{c \cdot \lambda}
\]

Most \([\alpha]\) values are quoted as \([\alpha]_D\) (where the D indicates the wavelength of 589 nm, the ‘D line’ of a sodium lamp) or \([\alpha]_{20}\), the 20 indicating 20 °C. These define the remaining variables.

Here is an example. A simple acid, known as mandelic acid, can be obtained from almonds in an enantiomerically pure form. When 28 mg was dissolved in 1 cm\(^3\) of ethanol and the solution placed in a 10-cm-long polarimeter cell, an optical rotation \(\alpha\) of –4.35° was measured (that is, 4.35° to the left) at 20 °C with light of wavelength 589 nm. What is the specific rotation of the acid?

First, we need to convert the concentration to grammes per cubic centimetre: 28 mg in 1 cm\(^3\) is the same as 0.028 g cm\(^{-3}\). The path length of 10 cm is 1 dm, so

\[
[\alpha]_D = \frac{-4.35}{0.028 \times 1} = -155.4
\]

**Enantiomers can be described as (+) or (–)**

We can use the fact that two enantiomers rotate plane-polarized light in opposite directions to assign each a label that doesn’t depend on knowing its configuration. We call the enantiomer that rotates plane-polarized light to the right (gives a positive rotation) the (+)-enantiomer (or the **dextrorotatory** enantiomer) and the enantiomer that rotates plane-polarized light to the left (gives a negative rotation) the (–)-enantiomer (or the **laevorotatory** enantiomer). The direction in which light is rotated is not dependent on whether a stereogenic centre is R or S. An (R) compound is equally as likely to be (+) as (–)—of course, if it is (+) then its (S) enantiomer must be (–). The enantiomer of mandelic acid we have just discussed, for example, is (R)-(–)-mandelic acid because its specific rotation is negative, and (S)-alanine happens to be (S)-(+)alanine. The labels (+) and (–) were more useful before the days of X-ray crystallography, when chemists did not know the actual configuration of the molecules they studied, and could distinguish two enantiomers only by the signs of their specific rotations.

**Enantiomers can be described as D or L**

Long before the appearance of X-ray crystallography as an analytical tool, chemists had to discover the detailed structure and stereochemistry of molecules by a complex series of degradations. A molecule was gradually broken down into its constituents, and from the products that were formed the overall structure of the starting molecule was deduced. As far as stereochemistry was concerned, it was possible to measure the specific rotation of a compound, but not to determine its configuration. However, by using series of degradations it was possible to tell whether certain compounds had the same or opposite configurations.

Glyceraldehyde is one of the simplest chiral compounds in nature. Because of this, chemists took it as the standard against which the configurations of other compounds could be compared. The two enantiomers of glyceraldehyde were given the labels D (for dextro—because it was the (+)-enantiomer) and L (for laev—because it was the (–)-enantiomer). Any enantiomerically pure compound that could be related, by a series of chemical degradations and transformations, to D-(+)glyceraldehyde was labelled D, and any compound that could be
related to \(\text{L}-(-)\)-glyceraldehyde was labelled \(\text{L}\). The processes concerned were slow and laborious (the scheme below shows how \((-)\)-lactic acid was shown to be \(\text{D}(-)\)-lactic acid) and are never used today. \(\text{D}\) and \(\text{L}\) are now used only for certain well-known natural molecules, where their use is established by tradition, for example, the \(\text{L}\)-amino acids or the \(\text{D}\)-sugars. These labels, \(\text{D}\) and \(\text{L}\), are in \textit{small capital} letters.

- Remember that the \(R/S\), \(+/-\), and \(\text{D/L}\) nomenclatures all arise from different observations and the fact that a molecule has, say, the \(R\) configuration gives no clue as to whether it will have \(+\) or \(-\) optical activity or be labelled \(\text{D}\) or \(\text{L}\). Never try and label a molecule as \(\text{D/L}\) or \(+/-\) simply by working it out from the structure. Likewise, never try and predict whether a molecule will have a \(+\) or \(-\) specific rotation by looking at the structure.

**The correlation between \(\text{D}(-)\)-lactic acid and \(\text{D}(+)-\)glyceraldehyde**

Here, for example, is the way that \((-)\)-lactic acid was shown to have the same configuration as \(\text{D}(-)\)-glyceraldehyde. We do not expect you to have come across the reactions used here.

\[
\begin{align*}
\text{D}(-)\text{-lactic acid} & \xrightarrow{\text{Na/Hg}} \text{(+)-isoserine} \\
\text{H}_2\text{N}-\text{CO}_2\text{H} & \xrightarrow{\text{HNO}_2, \text{HgO}} \text{HO}\text{-glyceric acid} \\
\text{CO}_2\text{H} & \xrightarrow{\text{HgO}} \text{D}(+)-\text{glyceraldehyde}
\end{align*}
\]

Notice from this scheme that the three intermediates all have the ‘same’ stereochemistry and yet one is \((R)\) and two are \((S)\). This is merely the consequence of the priority of the elements. \((R)\) can be \(\text{D}\) or \(\text{L}\) and \((+\) or \((-\).

**Diastereoisomers are stereoisomers that are not enantiomers**

Two enantiomers are chemically identical because they are mirror images of one another. Other types of stereoisomers may be chemically (and physically) quite different. These two alkenes, for example, are geometrical isomers (or \(\text{cis}–\text{trans}\) isomers). Their physical chemical properties are different, as you would expect, since they are quite different in shape. Neither is chiral of course as they are planar molecules.

\[
\begin{align*}
\text{HO}_2\text{C} & \xrightarrow{\text{fumaric acid}} \text{CO}_2\text{H} \\
\text{cis}-\text{butenedioic acid} & \xrightarrow{\text{maleic acid}} \text{cis} & \text{trans}-\text{butenedioic acid (fumaric acid)} & \text{m.p. 299–300 °C} \\
\nom{\text{cis}} & \text{trans} & \text{cis}-\text{butenedioic acid (maleic acid)} & \text{m.p. 140–142 °C}
\end{align*}
\]

A similar type of stereoisomerism can exist in cyclic compounds. In one of these, \(4\text{-t}-\text{butylcyclohexanols}\), the two substituents are on the same side of the ring; in the other, they are on opposite sides of the ring. Again, the two compounds have chemical and physical properties that are quite different.

\[
\begin{align*}
\text{cis 4-t-butylcyclohexanol} & \xrightarrow{\text{cis isomer}} \text{mp 82–83 °C} \\
\text{trans 4-t-butylcyclohexanol} & \xrightarrow{\text{trans isomer}} \text{mp 80–81 °C}
\end{align*}
\]

\(1^H\text{NMR: }\delta_H \text{ of green proton 4.02} \quad \text{cis isomer} \quad \delta_H \text{ of green proton 3.50} \text{trans isomer}

Stereoisomers that are not mirror images of one another are called \textit{diastereoisomers}. Both of these pairs of isomers fall into this category. Notice how the physical and chemical properties of a pair of diastereoisomers differ.

- The physical and chemical properties of enantiomers are identical; the physical and chemical properties of diastereoisomers differ. ‘Diastereoisomer’ is sometimes shortened to ‘diastereomer’.
Diastereoisomers can be chiral or achiral

This pair of epoxides was produced by chemists in Pennsylvania in the course of research on drugs intended to alleviate the symptoms of asthma. Clearly, they are again diastereoisomers, and again they have different properties. Although the reaction they were using to make these compounds gave some of each diastereoisomer, the chemists working on these compounds only wanted to use the first (trans) epoxide. They were able to separate it from its cis diastereoisomer by chromatography because the diastereoisomers differ in polarity.

\[
\text{trans epoxide} \quad \text{cis epoxide}
\]

This time, the diastereoisomers are a little more complex than the examples above. The first two pairs of diastereoisomers we looked at were achiral—they each had a plane of symmetry through the molecule.

Two pairs of achiral diastereoisomers

\[
\text{fumaric acid} \quad \text{maleic acid}
\]

The epoxide diastereoisomers, on the other hand, are chiral. We know this because they do not have a plane of symmetry and we can check that by drawing the mirror image of each one: it is not superimposable on the first structure.

\[
\text{structures have no plane of symmetry, so they must be chiral}
\]

If a compound is chiral, it can exist as two enantiomers. We’ve just drawn the two enantiomers of each of the diastereoisomers of our epoxide. This set of four structures contains two diastereoisomers (stereoisomers that are not mirror images). These are the two different chemical compounds, the cis and trans epoxides, that have different properties. Each can exist as two enantiomers (stereoisomers that are mirror images) indistinguishable except for rotation. We have two pairs of diastereoisomers, each being a pair of enantiomers. When you are considering the stereochemistry of a compound, always distinguish the diastereoisomers first and then split these into enantiomers if they are chiral.
In fact, the chemists working on these compounds wanted only one enantiomer of the \textit{trans} epoxide—the top left stereoisomer. They were able to separate the \textit{trans} epoxide from the \textit{cis} epoxide by chromatography because they are diastereoisomers. However, because they had made both diastereoisomers in the laboratory from achiral starting materials, both diastereoisomers were racemic mixtures of the two enantiomers. Separating the top enantiomer of the \textit{trans} epoxide from the bottom one was much harder because enantiomers have identical physical and chemical properties. To get just the enantiomer they wanted the chemists had to develop some completely different chemistry, using enantiomerically pure compounds derived from nature.

\textbf{Absolute and relative stereochemistry}

When we talk about two chiral diastereoisomers, we have no choice but to draw the structure of one enantiomer of each diastereoisomer because we need to include the stereochemical information to distinguish them, even if we’re talking about a racemic mixture of the two enantiomers. To avoid confusion, it’s best to write something definite under the structure, such as ‘±’ (meaning racemic) under a structure if it means ‘this diastereoisomer’ but not ‘this enantiomer of this diastereoisomer’. So in this case we should say that the chemists were able to separate these two diastereoisomers, but wanted only one enantiomer of the \textit{trans} diastereoisomer and that this could not be separated by physical means.

\begin{center}
\includegraphics[width=\textwidth]{diagram.png}
\end{center}

When the stereochemistry drawn on a molecule means ‘this diastereoisomer’, we say that we are representing relative stereochemistry; when it means ‘this enantiomer of this diastereoisomer’ we say we are representing its absolute stereochemistry. Relative stereochemistry tells us only how the stereogenic centres within a molecule relate to each other.

\begin{itemize}
\item \textbf{Enantiomers and diastereoisomers}
\end{itemize}

\begin{itemize}
\item Enantiomers are stereoisomers that are mirror images. A pair of enantiomers are mirror-image forms of the same compound and have opposite absolute stereochemistry.
\item Diastereoisomers are stereoisomers that are not mirror images. Two diastereoisomers are different compounds, and have different relative stereochemistry.
\item Diastereoisomers may be achiral (have a plane of symmetry) or they may be chiral (have no plane of symmetry).
\end{itemize}

\begin{center}
\includegraphics[width=\textwidth]{enantiomers_diagram.png}
\end{center}

\textbf{Diastereoisomers can arise when structures have more than one stereogenic centre}

Let’s analyse our set of four stereoisomers a little more closely. You may have already noticed that these structures all contain stereogenic centres—two in each case. Go back to the diagram of the four structures at the bottom of p. 312 and, without looking at the structures overleaf, assign an \textit{R} or \textit{S} label to each of the stereogenic centres.

You should have made assignments of \textit{R} and \textit{S} like this.

You need to know, and be able to use, the rules for assigning \textit{R} and \textit{S}; they were explained on p. 308. If you get any of the assignments wrong, make sure you understand why.
Converting enantiomers and diastereoisomers

- To go from one enantiomer to another, both stereogenic centres are inverted.
- To go from one diastereoisomer to another, only one of the two is inverted.

All the compounds that we have talked about so far have been cyclic because the diastereoisomers are easy to visualize: two diastereoisomers can be identified because the substituents are either on the same side or on opposite sides of the ring (cis or trans). But acyclic compounds can exist as diastereoisomers too. Take these two, for example. Both ephedrine and pseudoephedrine are members of the amphetamine class of stimulants, which act by imitating the action of the hormone adrenaline.

Ephedrine and pseudoephedrine are stereoisomers that are clearly not mirror images of each other—only one of the two stereogenic centres in ephedrine is inverted in pseudoephedrine—so they must be diastereoisomers. Thinking in terms of stereogenic centres is useful because, just as this compound has two stereogenic centres and can exist as two diastereoisomers, any compound with more than one stereogenic centre can exist in more than one diastereoisomeric form.

Both ephedrine and pseudoephedrine are produced in enantiomerically pure form by plants, so, unlike the anti-asthma intermediates above, in this case we are talking about single enantiomers of single diastereoisomers. Adrenaline (also known as epinephrine) is also chiral. In nature it is a single enantiomer but it cannot exist as other diastereoisomers as it has only one stereogenic centre.

Ephedrine and pseudoephedrine

Ephedrine is a component of the traditional Chinese remedy ‘Ma Huang’, extracted from Ephedra species. It is also used in nasal sprays as a decongestant. Pseudoephedrine is the active component of the decongestant Sudafed.

The ‘natural’ enantiomers of the two diastereomers are (−)-ephedrine and (+)pseudoephedrine, which does not tell you which is which, or (1R,2S)-(−)-ephedrine and (1S,2S)-(+)pseudoephedrine.
pseudoephedrine, which does. From that you should be able to deduce the corresponding structures.

Here are some data on \((1R,2S)-(\text{--})\)-ephedrine and \((1S,2S)-(\text{+})\)-pseudoephedrine and their ‘unnatural’ enantiomers (which have to be made in the laboratory), \((1S,2R)-(\text{+})\)-ephedrine and \((1R,2R)-(\text{--})\)-pseudoephedrine.

The two diastereoisomers are different compounds with different names and different properties, while the pairs of enantiomers are the same compound with the same properties, differing only in the direction in which they rotate polarized light.

We can illustrate the combination of two stereogenic centres in a compound by considering what happens when you shake hands with someone. Hand-shaking is successful only if you each use the same hand! By convention, this is your right hand, but it’s equally possible to shake left hands. The overall pattern of interaction between two right hands and two left hands is the same: a right-handshake and a left-handshake are enantiomers of one another; they differ only in being mirror images. If, however, you misguided try to shake your right hand with someone else’s left hand you end up holding hands. Held hands consist of one left and one right hand; a pair of held hands have totally different interactions from a pair of shaking hands; we can say that holding hands is a diastereoisomer of shaking hands. We can summarize the situation when we have two hands, or two chiral centres, each one \(R\) or \(S\).

What about compounds with more than two stereogenic centres? The family of sugars provides lots of examples. Ribose is a five-carbon sugar that contains three stereogenic centres. The enantiomer shown here is the one used in the metabolism of all living things and, by convention, is known as \(d\)-ribose. The three stereogenic centres of \(d\)-ribose have the \(R\) configuration. For convenience, we will consider ribose in its open-chain form, but more usually it would be cyclic, as shown underneath.

\[ \text{Remember that } (\text{+}) \text{ and } (\text{--}) \text{ refer to the sign of the specific rotation, while } R \text{ and } S \text{ are derived simply by looking at the structure of the compounds. There is no simple connection between the two!} \]
In theory we can work out how many ‘stereoisomers’ there are of a compound with three stereogenic centres simply by noting that there are $8 (= 2^3)$ ways of arranging Rs and Ss.

\[
\begin{array}{cccc}
RRR & RRS & RSR & RSS \\
SSS & SSR & SRS & SRR
\end{array}
\]

But this method blurs the all-important distinction between diastereoisomers and enantiomers. In each case, the combination in the top row and the combination directly below it are enantiomers (all three centres are inverted); the four columns are diastereoisomers. Three stereogenic centres therefore give four diastereoisomers, each a pair of two enantiomers. Going back to the example of the $C_3$ aldoses, each of these diastereoisomers is a different sugar. In these diagrams each diastereoisomer is in a frame but the top line shows one enantiomer (D) and the bottom line the other (L).

**Structure of sugars**

A sugar has the empirical formula $C_nH_{2n}O_n$ and consists of a chain of carbon atoms, one being a carbonyl group and the rest carrying OH groups. If the carbonyl group is at the end of the chain (in other words, it is an aldehyde), the sugar is an aldose. If the carbonyl group is not at the end of the chain, the sugar is a ketose. We come back to all this in detail in Chapter 42. The number of carbon atoms, $n$, can be 3–8: aldoses have $n - 2$ stereogenic centres and ketoses $n - 3$ stereogenic centres. In fact, most sugars exist as an equilibrium mixture of this open-chain structure and a cyclic hemiacetal isomer (Chapter 6).

You’ve probably recognized that there’s a simple mathematical relationship between the number of stereogenic centres and the number of stereoisomers a structure can have. Usually, a structure with $n$ stereogenic centres can exist as $2^n$ stereoisomers. These stereoisomers consist of $2^{n-1}$ diastereoisomers, each of which has a pair of enantiomers.

**Fischer projections**

The stereochemistry of sugars used to be represented by Fischer projections. The carbon backbone was laid out in a vertical line and twisted in such a way that all the substituents pointed towards the viewer. Fischer projections are so unlike real molecules that you should never use them. However, you may see them in older books, and you should have an idea about how to interpret them. Just remember that all the branches down the side of the central trunk are effectively bold wedges (coming towards the viewer), while the central trunk lies in the plane of the paper. By mentally twisting the backbone into a realistic zig-zag shape you should end up with a reasonable representation of the sugar molecule.
**Why only usually?—achiral compounds with more than one stereogenic centre**

Sometimes, symmetry in a molecule can cause some stereoisomers to be degenerate, or ‘cancel out’—there aren’t as many stereoisomers as you’d expect. Take tartaric acid, for example. This stereoisomer of tartaric acid is found in grapes, and its salt, potassium hydrogen tartrate, can precipitate out as crystals at the bottom of bottles of wine. It has two stereogenic centres, so you’d expect $2^2 = 4$ stereoisomers; two diastereoisomers, each a pair of enantiomers.

![Interactive stereoisomers of tartaric acid](image)

While the pair of structures on the left are certainly enantiomers, if you look carefully at the pair of structures on the right, you’ll see that they are, in fact, not enantiomers but identical structures. To prove it, just rotate the top one through 180° in the plane of the paper.

(1R,2S)-Tartaric acid and (1S,2R)-tartaric acid are not enantiomers, but they are identical because, even though they contain stereogenic centres, they are achiral. By drawing (1R,2S)-tartaric acid after a 180° rotation about the central bond, you can easily see that it has a mirror plane, and so must be achiral. Since the molecule has a plane of symmetry, and R is the mirror image of S, the R,S diastereoisomer cannot be chiral.

![Interactive display of meso form of tartaric acid](image)

**Compounds that contain stereogenic centres but are themselves achiral are called meso compounds.** This means that there is a plane of symmetry with R stereochemistry on one side and S stereochemistry on the other.

So tartaric acid can exist as two diastereoisomers, one with two enantiomers and the other achiral (a meso compound). It’s worth noting that the formula stating that a compound with $n$ stereogenic centres has $2^{n-1}$ diastereoisomers has worked but not the formula that states there are $2^n$ ‘stereoisomers’. In general, it’s safer not to count up total ‘stereoisomers’ but to work out first how many diastereoisomers there are, and then to decide whether or not each one is chiral, and therefore whether or not it has a pair of enantiomers.

**Meso hand-shaking**

We can extend our analogy between hand-shaking and diastereoisomers to meso compounds as well. Imagine a pair of identical twins shaking hands. They could be shaking their left hands or their right hands and there would be a way to tell the two handshakes apart because they are enantiomers. But if the twins hold hands, you will not be able to distinguish left holds right from right holds left, because the twins themselves are indistinguishable—this is the meso hand-hold!

Meso diastereoisomers of inositol

Look out for meso diastereoisomers in compounds that have a degree of symmetry in their overall structure. Inositol, one of whose diastereoisomers is an important growth factor, has six stereogenic centres. It’s a challenge to work out how many diastereoisomers it has—in fact all but one of them are meso.

Investigating the stereochemistry of a compound

When you want to describe the stereochemistry of a compound our advice is to identify the diastereoisomers and then think about whether they are chiral or not. Don’t just count up ‘stereoisomers’—to say that a compound with two stereogenic centres has four ‘stereoisomers’ is rather like saying that ‘four hands are getting married’. Two people are getting married, each with two hands.

Let’s work through how you might think about the stereochemistry of a simple example, the linear triol 2,3,4-trihydroxypentane or pentane-2,3,4-triol.

This is what you should do.

1. Draw the compound with the carbon skeleton in the usual zig-zag fashion running across the page, 1.

2. Identify the chiral centres, 2.

3. Decide how many diastereoisomers there are by putting the substituents at those centres up or down. It often helps to give each diastereoisomer a ‘tag’ name. In this case there are three diastereoisomers. The three OH groups can be all on the same side or else one of the end OHs or the middle one can be on the opposite side to the rest. We can call the first syn,syn because the two pairs of chiral centres (1 & 2, and 2 & 3) groups are both arranged with the OHs on the same side of the molecule (syn).

4. By checking on possible planes of symmetry, see which diastereoisomers are chiral. In this case only the plane down the centre can be a plane of symmetry.

5. Draw the enantiomers of any chiral diastereoisomer by inverting all the stereogenic centres. This can easily be achieved by reflecting the molecule in the plane of the paper, as if it were a mirror. Everything that was ‘up’ is now ‘down’ and vice versa.

6. Announce the conclusion. You could have said that there are four ‘stereoisomers’ but the following statement is much more helpful. There are three diastereoisomers, the syn,syn, the syn,anti, and the anti,anti. The syn,syn and the anti,anti are achiral (meso) compounds but the syn,anti is chiral and has two enantiomers.
The mystery of Feist’s acid

It is hard nowadays to realize how difficult structure solving was before the days of spectroscopy. A celebrated case was that of ‘Feist’s acid’, discovered by Feist in 1893 from a deceptively simple reaction. Early work without spectra led to two suggestions for its structure, both based on a three-membered ring, which gave the compound some fame because unsaturated three-membered rings were rare. The favoured structure was the cyclopropene.

The argument was still going on in the 1950s when the first NMR spectrometers appeared. Although infrared appeared to support the cyclopropene structure, one of the first problems resolved by the primitive 40 MHz instruments available was that of Feist’s acid, which had no methyl group signal but did have two protons on a double bond and so had to be the exomethylene isomer after all.

This structure has two chiral centres, so how will we know which diastereoisomer we have? The answer was simple: the stereochemistry has to be trans because Feist’s acid is chiral: it can be resolved (see later in this chapter) into two enantiomers. Now, the cis diacid would have a plane of symmetry, and so would be achiral—it would be a meso compound. The trans acid on the other hand is chiral. If you do not see this, try superimposing it on its mirror image—you will find that you cannot. In fact, Feist’s acid has an axis of symmetry, and you will see shortly that axes of symmetry are compatible with chirality.

Modern NMR spectra make the structure easy to deduce. There are only two proton signals as the CO$_2$H protons exchange in the DMSO solvent needed. The two protons on the double bond are identical (5.60 ppm) and so are the two protons on the three-membered ring, which come at the expected high field (2.67 ppm). There are four carbon signals: the C=O at 170 ppm, two alkene signals between 100 and 150 ppm, and the two identical carbons in the three-membered ring at 25.45 ppm.

Chiral compounds with no stereogenic centres

A few compounds are chiral, yet have no stereogenic centres. Try making a model of the allene in the margin. It has no stereogenic centre, but these mirror images are not superimposable and so the allene is chiral: the structures shown are enantiomers. Similarly, some biaryl compounds, such as the important bisphosphine below, known as BINAP, exist as two separate enantiomers because rotation about the green bond is restricted. If you were to look at this molecule straight down along the green bond, you would see that the two flat rings are at right angles to each other and so the molecule has a twist in it rather like the 90° twist in the allene. Compounds that are chiral because of restricted rotation about a single bond are called atropisomers (from the Greek for ‘won’t turn’).
These two examples rely on the rigidity of \( \pi \) systems but this simple saturated system is also chiral. These two rings have to be orthogonal because of the tetrahedral nature of the central carbon atom. There is no chiral centre, but there is no plane of symmetry. Cyclic compounds like this with rings joined at a single C atom are called spiro compounds. Spiro compounds are often chiral even when at a first glance they look quite symmetrical, and you should look particularly carefully for planes of symmetry when you think about their stereochemistry.

**Axes and centres of symmetry**

The fact that the three compounds we have just introduced (along with Feist's acid in the box on p. 319) were chiral might have surprised you, because at first glance they do look quite ‘symmetrical’. In fact, they do all have an element of symmetry, and it is only one which is compatible with chirality: an axis of symmetry. If a molecule can be rotated through 180° about an axis to give exactly the same structure then it has twofold axial symmetry, or \( C_2 \) symmetry. Compounds with an axis of symmetry will still be chiral, provided they lack either a plane or a centre of symmetry.

\( C_2 \) symmetry is common in many more everyday molecules than the ones in the last section. Below is an example of a compound with two diastereoisomers. One (we call it the *syn* diastereoisomer here—the two phenyl rings are on the same side) has a plane of symmetry—it must be achiral (and as it nonetheless has chiral centres we can also call it the *meso* diastereoisomer). The other has some degree of symmetry, but it has axial symmetry and can therefore be chiral. The \( C_2 \) axis of symmetry is shown in orange. Rotating 180° gives back the same structure, but reflecting in a mirror plane (brown) gives a non-superimposable mirror image.

So far we have used a *plane of symmetry* as the defining characteristic of an achiral molecule: we have said several times that a molecule is chiral if it lacks a plane of symmetry. We are now
going to introduce a second type of symmetry that is not compatible with chirality. If a molecule has a *centre of symmetry* it is not chiral. We will now explain how to spot a centre of symmetry.

The diamide skeleton in the margin has a plane of symmetry in the plane of the page and also a plane of symmetry at right angles to that plane passing through the two saturated carbon atoms (represented by the green dotted line). If we add substituents R to this structure we can have two diastereoisomers with the two R groups on the same side (*syn*) of the flat ring or on opposite (*anti*) sides. Although the plane of the paper is no longer a plane of symmetry, neither isomer is chiral as the other plane bisects the substituents and is still a plane of symmetry. So far nothing new.

Now consider the related double amide below. The plane of the page is again a plane of symmetry but there is now no plane of symmetry at right angles. This heterocycle is called a ‘diketopiperazine’ and can be made by dimerizing an amino acid: the compound in the margin is the dimer of glycine. With substituted amino acids, such as those below where $R \neq H$, there are again two diastereoisomers, *syn* and *anti*. But their symmetry properties are different. The *syn* isomer is chiral but the *anti* isomer is not.

The *syn* diastereoisomer has no plane of symmetry but you should be able to spot a $C_2$ axis of symmetry running straight through the middle of the ring. The axis is compatible with chirality of course. In this compound both chiral centres are $S$ and it has an enantiomer where both are $R$.

The *anti* diastereoisomer has no plane of symmetry, nor does it have an axis. Instead it has a *centre of symmetry*. This is marked with a black dot in the middle of the molecule and means that if you go in any direction from this centre and meet, say, an R group, you will meet the same thing if you go in the opposite direction (green arrows). The same thing applies to the brown arrows and, of course, to the ring itself. There is no centre of symmetry in the *syn* isomer as the green or brown arrows would point to R on one side and H on the other. The *anti* isomer is superimposable on its mirror image and is achiral.
Chirality in terms of planes, centres, and axes of symmetry

- Any molecule which has a plane of symmetry or a centre of symmetry is achiral.
- Any molecule which has an axis of symmetry is chiral, provided it does not also have a plane or a centre of symmetry. An axis of symmetry is the only symmetry element compatible with chirality.

Separating enantiomers is called resolution

Early in this chapter we said that most of the molecules in Nature are chiral, and that Nature usually produces these molecules as single enantiomers. We’ve talked about the amino acids, the sugars, ephedrine, pseudoephedrine, and tartaric acid—all compounds that can be isolated from natural sources as single enantiomers. On the other hand, in the laboratory, if we make chiral compounds from achiral starting materials we are doomed to get racemic mixtures. So how do chemists ever isolate compounds as single enantiomers, other than by extracting them from natural sources? We’ll consider this question in much more detail in Chapter 41, but here we will look at the simplest way: using Nature’s enantiomerically pure compounds to help us separate the components of a racemic mixture into its two enantiomers. This process is called resolution. Imagine the reaction between a chiral, but racemic, alcohol and a chiral, but racemic, carboxylic acid, to give an ester in an ordinary acid-catalysed esterification (Chapter 10).

The product contains two chiral centres, so we expect to get two diastereoisomers, each a racemic mixture of two enantiomers. Diastereoisomers have different physical properties, so they should be easy to separate, for example by chromatography.

We could then reverse the esterification step and hydrolyse either of these diastereoisomers, to regenerate racemic alcohol and racemic acid.

Remember that (±) means the compounds are racemic: we’re showing only relative, not absolute, stereochemistry.
If we repeat this reaction, this time using an enantiomerically pure sample of the acid, available from (R)-mandelic acid, the almond extract you met on p. 310, we will again get two diastereoisomeric products, but this time each one will be enantiomerically pure. Note that the stereochemistry shown here is absolute stereochemistry.

\[
\begin{align*}
\text{OH} & \quad \text{H}_2\text{O} \\
\text{Ph} & \quad \text{H}^+ \\
\text{HO}_2\text{C} & \quad \text{Ph} \\
\text{OMe} & \quad \text{Ph} \\
\text{OMe} & \quad \text{Ph} \\
\end{align*}
\]

If we now hydrolyse each diastereoisomer separately, we have done something rather remarkable: we have managed to separate two enantiomers of the starting alcohol.

A separation of two enantiomers is called a **resolution**. Resolutions can be carried out only if we make use of a component that is already enantiomerically pure: it is very useful that Nature provides us with such compounds; resolutions nearly always make use of compounds derived from nature.

**Natural chirality**

Why Nature uses only one enantiomer of most important biochemicals is an easier question to answer than how this asymmetry came about in the first place, or why l-amino acids and d-sugars were the favoured enantiomers, since, for example, proteins made out of racemic samples of amino acids would be complicated by the possibility of enormous numbers of diastereomers. Some have suggested that life arose on the surface of single chiral quartz crystals, which provided the asymmetric environment needed to make life’s molecules enantiomerically pure. Or perhaps the asymmetry present in the spin of electrons released as gamma rays acted as a source of molecular asymmetry. Given that enantiomerically pure living systems should be simpler than racemic ones, maybe it was just chance that the l-amino acids and the d-sugars won out.

Now for a real example. Chemists studying the role of amino acids in brain function needed to obtain each of the two enantiomers of the amino acid in the margin. They made a racemic sample using the Strecker synthesis of amino acids that you met in Chapter 11. The racemic amino acid was treated with acetic anhydride to make the mixed anhydride and then with the sodium salt of naturally derived, enantiomerically pure alcohol menthol to give two diastereoisomers of the ester.

One of the diastereoisomers turned out to be more crystalline (that is, to have a higher melting point) than the other and, by allowing the mixture to crystallize, the chemists were able to isolate a pure sample of this diastereoisomer. Evaporating the diastereoisomer left in solution (the ‘mother liquor’) gave them the less crystalline diastereoisomer.
Next the esters were hydrolysed by boiling them in aqueous KOH. The acids obtained were enantiomers, as shown by their (nearly) opposite optical rotations and similar melting points. Finally, a more vigorous hydrolysis of the amides (boiling for 40 hours with 20% NaOH) gave them the amino acids they required for their biological studies (see bottom of p. 322).

Note that the rotations of the pure diastereoisomers were not equal and opposite. These are single enantiomers of different compounds and there is no reason for them to have the same rotation.

Resolutions using diastereoisomeric salts

The key point about resolution is that we must bring together two stereogenic centres in such a way that there is a degree of interaction between them: separable diastereoisomers are created from inseparable enantiomers. In the last two examples, the stereogenic centres were brought together in covalent compounds, esters. Ionic compounds will do just as well—in fact, they are often better because it is easier to recover the compound after the resolution.
An important example is the resolution of the enantiomers of naproxen. Naproxen is a member of a family of compounds known as non-steroidal anti-inflammatory drugs (NSAIDs) which are 2-aryl propionic acids. This class also includes ibuprofen, the painkiller developed by Boots and marketed as Nurofen.

Both naproxen and ibuprofen are chiral but, while both enantiomers of ibuprofen are effective painkillers, and the drug is sold as a racemic mixture (and anyway racemizes in the body) only the (S) enantiomer of naproxen has anti-inflammatory activity. When the American pharmaceutical company Syntex first marketed the drug they needed a way of resolving the racemic naproxen they synthesized in the laboratory.

Since naproxen is a carboxylic acid, they chose to make the carboxylate salt of an enantiomerically pure amine, and found that the most effective was a glucose derivative. Crystals were formed, which consisted of the salt of the amine and (S)-naproxen, the salt of the amine with (R)-naproxen (the diastereoisomer of the crystalline salt) being more soluble and so remaining in solution. These crystals were filtered off and treated with base, releasing the amine (which can later be recovered and reused) and allowing the (S)-naproxen to crystallize as its sodium salt. This is an unusual resolving agent as a simpler amine might usually be preferred. However, it makes the point that many resolving agents may have to be tried before one is found that works.

You may consider it strange that it was necessary to market naproxen as a single enantiomer, in view of what we have said about enantiomers having identical properties. The two enantiomers of naproxen do indeed have identical properties in the laboratory, but once they are inside a living system they, and any other chiral molecules, are differentiated by interactions with the enantiomerically pure molecules they find there. An analogy is that of a pair of gloves—the gloves weigh the same, are made of the same material, and have the same colour—in these respects they are identical. But interact them with a chiral environment, such as a hand, and they become differentiable because only one fits.
The way in which drugs interact with receptors mirrors this hand-and-glove analogy quite closely. Drug receptors, into which drug molecules fit like hands in gloves, are nearly always protein molecules, which are enantiomerically pure because they are made up of just l-amino acids. One enantiomer of a drug is likely to interact much better than the other, or perhaps in a different way altogether, so the two enantiomers of chiral drugs often have quite different pharmacological effects. In the case of naproxen, the (S)-enantiomer is 28 times as effective as the (R). Ibuprofen, on the other hand, is still marketed as a racemate because the compound racemizes in the bloodstream.

Sometimes, the enantiomers of a drug may have completely different therapeutic properties. One example is Darvon, which is a painkiller. Its enantiomer, known as Novrad, is an anticough agent. Notice how the enantiomeric relationship between these two drugs extends beyond their chemical structures! In Chapter 41 we will talk about other cases where two enantiomers have quite different biological effects.

**Resolutions can be carried out by chromatography on chiral materials**

Interactions even weaker than ionic bonds can be used to separate enantiomers. Chromatographic separation relies on a difference in affinity between a stationary phase (often silica) and a mobile phase (the solvent travelling through the stationary phase, known as the eluent) mediated by, for example, hydrogen bonds or van der Waals interactions. If the stationary phase is made chiral by bonding it with an enantiomerically pure compound (often a derivative of an amino acid), chromatography can be used to separate enantiomers.

Chromatography on a chiral stationary phase is especially important when the compounds being resolved have no functional groups suitable for making the derivatives (usually esters or salts) needed for the more classical resolutions described above. For example, the two enantiomers of an analogue of the tranquillizer Valium were found to have quite different biological activities.
In order to study these compounds further, it was necessary to obtain them in enantiomerically pure form. This was done by passing a solution of the racemic compound through a column of silica bonded to an amino-acid-derived chiral stationary phase. The \((R)-(-)\)-enantiomer showed a lower affinity for the stationary phase and therefore was eluted from the column first, followed by the \((S)-(+)-\)enantiomer.

Two enantiomers of one molecule may be the same compound, but they are clearly different, although only in a limited number of situations. They can interact with biological systems differently, for example, and can form salts or compounds with different properties when reacted with a single enantiomer of another compound. In essence, enantiomers behave identically except when they are placed in a chiral environment. In Chapter 41 we will see how to use this fact to make single enantiomers of chiral compounds, but next we move on to three classes of reactions in which stereochemistry plays a key role: substitutions, eliminations, and additions.

**Further reading**

**Check your understanding**

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Mechanisms for nucleophilic substitution

Substitution is the replacement of one group by another. You met such reactions in Chapter 10, and an example is shown in the margin. This reaction is a substitution because the Cl group is replaced by the NH2 group. You learnt to call the molecule of ammonia (NH3) the nucleophile and the chloride you called the leaving group. In Chapter 10, the substitution reactions always took place at the trigonal (sp2) carbon atom of a carbonyl group.

In this chapter we shall be looking at reactions such as the second reaction in the margin. These are substitution reactions, because the Cl group is replaced by the PhS group. But the CH2 group at which the reaction takes place is a tetrahedral (sp3), or saturated, carbon atom, rather than a C=O group. This reaction and the one above may look superficially the same but they are quite different in mechanism. The requirements of good reagents are also different in substitutions at carbonyl groups and at saturated carbon—that’s why we changed the nucleophile from NH3 to PhS: ammonia would not give a good yield of PhCH2NH2 in the second reaction.

Let’s have a look at why the mechanisms of the two substitutions must be different. Here’s a summary of the mechanism of the first reaction.
In the first step the nucleophile attacks the $\text{C}=\text{O}$ $\pi$ bond. It’s immediately obvious that the first step is no longer possible at a saturated carbon atom. The electrons cannot be added to a $\pi$ bond as the CH$_2$ group is fully saturated. In fact there is no way for the nucleophile to add before the leaving group departs (as it did in the reaction above) because this would give an impossible five-valent carbon atom.

Instead, two new and different mechanisms become possible. Either the leaving group goes first and the nucleophile comes in later, or the two events happen at the same time. The first of these possibilities you will learn to call the $\text{SN}_1$ mechanism. The second mechanism, which shows how the neutral carbon atom can accept electrons provided it loses some at the same time, you will learn to call the $\text{SN}_2$ mechanism. You will see later that both mechanisms are possible with this molecule, benzyl chloride.

**Why is it important to know about the two mechanisms for substitution?**

If we know which mechanism a compound reacts by, we know what sort of conditions to use to get good yields in substitutions. For example, if you look at a commonly used nucleophilic substitution, the replacement of OH by Br, you’ll find that two quite different reaction conditions are used depending on the structure of the alcohol. Tertiary alcohols react rapidly with HBr to give tertiary alkyl bromides. Primary alcohols, on the other hand, react only very slowly with HBr and are usually converted to primary alkyl bromides with PBr$_3$. The reason is that the first example is an $\text{SN}_1$ reaction while the second is an $\text{SN}_2$ reaction: by the end of this chapter you will have a clear picture of how to predict which mechanism will apply and how to choose appropriate reaction conditions.

**Kinetic evidence for the $\text{SN}_1$ and $\text{SN}_2$ mechanisms**

Before we go any further we are going to look in a bit more detail at these two mechanisms because they allow us to explain and predict many aspects of substitution reactions. The evidence that convinced chemists that there are two different mechanisms for substitution at saturated carbon is kinetic: it relates to the rate of reactions such as the displacement of bromide by hydroxide, as shown in the margin.

It was discovered, chiefly by Hughes and Ingold in the 1930s, that some nucleophilic substitutions are first order (that is, the rate depends only on the concentration of the alkyl halide...
and does not depend on the concentration of the nucleophile), while others are second order (the rate depends on the concentrations of both the alkyl halide and the nucleophile). How can we explain this result? In what we called the ‘SN2 mechanism’ on p. 329 there is just one step. Here’s the one-step SN2 mechanism for substitution of n-butyl bromide by hydroxide:

\[
\text{Br}^- + \text{HO}^- \rightarrow \text{BrO}^- + \text{HO}^- + \text{n-Bu}^+
\]

With only one step, that step must be the rate-determining step. The rate of the overall reaction depends only on the rate of this step, and kinetic theory tells us that the rate of a reaction is proportional to the concentrations of the reacting species:

\[
\text{rate of reaction} = k[n-\text{BuBr}][\text{HO}^-]
\]

If this mechanism is right, then the rate of the reaction will be simply and linearly proportional to both [n-BuBr] and [HO−]. And it is. Ingold measured the rates of reactions like these and found that they were proportional to the concentration of each reactant—in other words they were second order. He called this mechanism Substitution, Nucleophilic, 2nd order; SN2 for short. The rate equation is usually given like this, with \(k_2\) representing the second-order rate constant.

\[
\text{rate} = k_2[n-\text{BuBr}][\text{HO}^-]
\]

**Significance of the SN2 rate equation**

This equation is useful for two reasons. Firstly, it gives us a test for the SN2 mechanism. Let’s illustrate this with another example: the reaction between NaSMe (an ionic solid—the nucleophile will be the anion MeS−) and MeI to give Me2S, dimethyl sulfide.

To study the rate equation, first, we keep the concentration of NaSMe constant and in a series of experiments vary that of MeI and see what happens to the rate. Then in another set of experiments we keep the concentration of MeI constant and vary that of MeSNa and see what happened to the rate. If the reaction is indeed SN2 we should get a linear relationship in both cases: the graphs in the margin show a typical set of results.

The first graph tells us that the rate is proportional to [MeI], that is, rate = \(k_a\)[MeI] and the second graph that it is proportional to [MeSNa], that is, rate = \(k_b\)[MeSNa]. But why are the slopes different? If you look at the rate equation for the reaction, you will see that we have incorporated a constant concentration of one of the reagents into what appears to be the rate constant for the reaction. The true rate equation is

\[
\text{rate} = k_2[n-\text{BuBr}][\text{HO}^-]
\]

If [MeSNa] is constant, the equation becomes

\[
\text{rate} = k_a[\text{MeI}], \text{ where } k_a = k_2[\text{MeSNa}]
\]

If [MeI] is constant, the equation becomes

\[
\text{rate} = k_b[\text{MeSNa}], \text{ where } k_b = k_2[\text{MeI}]
\]

If you examine the graphs you will see that the slopes are different because

\[
\text{slope 1} = k_a = k_2[\text{MeSNa}], \text{ but slope 2} = k_b = k_2[\text{MeI}]
\]

We can easily measure the true rate constant \(k_2\) from these slopes because we know the constant values for [MeSNa] in the first experiment and for [MeI] in the second. The value of \(k_2\)
from both experiments should be the same. The mechanism for this reaction is indeed $S_{N2}$: the nucleophile $\text{MeS}^-$ attacks as the leaving group $\Gamma$ leaves.

The second reason that the $S_{N2}$ rate equation is useful is that it confirms that the performance of an $S_{N2}$ reaction depends both on the nucleophile and on the carbon electrophile. We can therefore make a reaction go better (speed it up or improve its yield) by changing either. For example, if we want to displace $\Gamma$ from $\text{MeI}$ using an oxygen nucleophile we might consider using any of those in the table below.

### Oxygen nucleophiles in the $S_{N2}$ reaction

<table>
<thead>
<tr>
<th>Oxygen nucleophile</th>
<th>$pK_a$ of conjugate acid</th>
<th>Rate in $S_{N2}$ reaction</th>

<td>0 ($\text{RSO}_2\text{OH}$)</td>
<td>slow</td>
</tr>
</tbody>
</table>

The same reasons that made hydroxide ion basic (chiefly that it is unstable as an anion and therefore reactive) make it a good nucleophile. Basicity can be viewed as nucleophilicity towards a proton, and nucleophilicity towards carbon must be related. So if we want a fast reaction, we should use NaOH rather than, say, $\text{Na}_2\text{SO}_4$ to provide the nucleophile. Even at the same concentration, the rate constant $k_2$ with $\text{HO}^-$ as the nucleophile is much greater than the $k_2$ with $\text{SO}_4^-$ as the nucleophile.

But that is not our only option. The reactivity and hence the structure of the carbon electrophile matter too. If we want reaction at a methyl group we can’t change the carbon skeleton, but we can change the leaving group. The table below shows what happens if we use the various methyl halides in reaction with NaOH. The best choice for a fast reaction (greatest value of $k_2$) will be to use $\text{MeI}$ and NaOH to give methanol.

- The rate of an $S_{N2}$ reaction depends on:
  - the nucleophile
  - the carbon skeleton
  - the leaving group

  along with the usual factors of temperature and solvent.

### Significance of the $S_{N1}$ rate equation

If we replace the substitution of $n$-butyl bromide with a substitution of $\text{t}$-butyl bromide, we get the reaction shown in the margin. It turns out that, kinetically, this reaction is first order: its rate depends only on the concentration of $\text{t}$-butyl bromide—but doesn’t matter how much hydroxide you add: the rate equation is simply...
The reason for this is that the reaction happens in two steps: first the bromide leaves, to generate a carbocation, and only then does the hydroxide ion move in to attack, forming the alcohol.

\[
\text{rate} = k_1 [t\text{-BuBr}]
\]

In the $S_N1$ mechanism, the formation of the cation is the rate-determining step. This makes good sense: a carbocation is an unstable species and so it will be formed slowly from a stable neutral organic molecule. But once formed, being very reactive, all its reactions will be fast, regardless of the nucleophile. The rate of disappearance of $t\text{-BuBr}$ is therefore simply the rate of the slow first step: the hydroxide nucleophile is not involved in this step and therefore does not appear in the rate equation and hence cannot affect the rate. If this is not clear to you, think of a crowd of people trying to leave a railway station or a football match through some turnstiles. It doesn't matter how fast they walk, run, or are driven away in taxis afterwards, it is only the rate of struggling through the turnstiles that determines how fast the station or stadium empties.

Once again, this rate equation is useful because we can determine whether a reaction is $S_N1$ or $S_N2$. We can plot the same graphs as we plotted before. If the reaction is $S_N2$, the graphs look like those we have just seen. But if it is $S_N1$, the graphs in the margin show what happens when we vary $t\text{-BuBr}$ at constant $[\text{NaOH}]$ and then vary $[\text{NaOH}]$ at constant $[t\text{-BuBr}]$.

The slope of the first graph is simply the first-order rate constant because rate $= k_1 [t\text{-BuBr}]$. But the slope of the second graph is zero. The rate-determining step does not involve NaOH so adding more of it does not speed up the reaction. The reaction shows first-order kinetics (the rate is proportional to one concentration only) and the mechanism is called $S_N1$, that is, Substitution, Nucleophilic, 1st order.

This observation is very significant. The fact that the nucleophile does not appear in the rate equation means that not only does its concentration not matter—its reactivity doesn't matter either! We are wasting our time opening a tub of NaOH to add to this reaction—water will do just as well. All the oxygen nucleophiles in the table above react at the same rate with $t\text{-BuBr}$ although they react at very different rates with MeI. Indeed, $S_N1$ substitution reactions are generally best done with weaker, non-basic nucleophiles to avoid the competing elimination reactions discussed in Chapter 17.

**The rate of an $S_N1$ reaction depends on:**

- the carbon skeleton
- the leaving group

along with the usual factors of temperature and solvent.

But NOT the nucleophile.

**How can we decide which mechanism ($S_N1$ or $S_N2$) will apply to a given organic compound?**

So, substitution reactions at saturated C go via one of two alternative mechanisms, each with a very different dependence on the nature of the nucleophile. It's important to be able to predict which mechanism is likely to apply to any reaction, and rather than doing the kinetic experiments to find out, we can give you a few simple pointers to predict which will operate
in which case. The factors that affect the mechanism of the reaction also help to explain why that mechanism operates.

The most important factor is the structure of the carbon skeleton. A helpful generalization is that compounds that can form relatively stable carbocations generally do so and react by the $S_N1$ mechanism, while the others have no choice but to react by the $S_N2$ mechanism. As you will see in a moment, the most stable carbocations are the ones that have the most substituents, so the more carbon substituents at the reaction centre, the more likely the compound is to react by the $S_N1$ mechanism.

As it happens, the structural factors that make cations stable usually also lead to slower $S_N2$ reactions. Heavily substituted compounds are good in $S_N1$ reactions, but bad in an $S_N2$ reaction because the nucleophile would have to squeeze its way into the reaction centre past the substituents. It is better for an $S_N2$ reaction if there are only hydrogen atoms at the reaction centre—methyl groups react fastest by the $S_N2$ mechanism. The effects of the simplest structural variations are summarized in the table below (where $R$ is a simple alkyl group like methyl or ethyl).

The only doubtful case is the secondary alkyl derivative, which can react by either mechanism, although it is not very good at either. The first question you should ask when faced with a new nucleophilic substitution is this ‘Is the carbon electrophile methyl, primary, secondary, or tertiary?’ This will start you off on the right foot, which is why we introduced these important structural terms in Chapter 2.

Later in this chapter we will look in more detail at the differences between the two mechanisms and the structures that favour each, but all of what we say will build on the table above.

**A closer look at the $S_N1$ reaction**

In our discussion of the $S_N1$ reaction above, we proposed the $t$-butyl carbocation as a reasonable intermediate formed by loss of bromide from $t$-butyl bromide. We now need to explain the evidence we have that carbocations can indeed exist, and the reasons why the $t$-butyl carbocation is much more stable than, for example, the $n$-butyl cation.

In Chapter 12 we introduced the idea of using a reaction energy profile diagram to follow the progress of a reaction from starting materials to products, via transition states and any intermediates. The energy profile diagram for the $S_N1$ reaction between $t$-butyl bromide and water looks something like this:
The carbocation is shown as an intermediate—a species with a finite (if short) lifetime for reasons we shall describe shortly. And because we know that the first step, the formation of the carbocation, is slow, that must be the step with the higher energy transition state. The energy of that transition state, which determines the overall rate of the reaction, is closely linked to the stability of the carbocation intermediate, and it is for this reason that the most important factor in determining the efficiency of an SN1 reaction is the stability or otherwise of any carbocation that might be formed as an intermediate.

**Shape and stability of carbocations**

We discussed the planar shape of the methyl cation in Chapter 4 (p. 103), and the tert-butyl cation is similar in structure: the electron-deficient central carbon atom has only six electrons, which it uses to form three σ bonds, and therefore also carries an empty p orbital. Any carbocation will have a planar carbon atom with an empty p orbital. Think of it this way: only filled orbitals contribute to the energy of a molecule, so if you have to have an unfilled orbital (which a carbocation always does) it is best to make that unfilled orbital as high in energy as possible to keep the filled orbitals low in energy. p orbitals are higher in energy than s orbitals (or hybrid sp, sp², or sp³ orbitals for that matter) so the carbocation always keeps the p orbital empty.

We know that the tert-butyl cation is stable enough to observe because of the work of George Olah, who won the Nobel Prize for Chemistry in 1994. The challenge is that carbocations are very reactive electrophiles, so Olah’s idea was to have a solution containing no nucleophiles. Any cation must have an anion to balance the charge, so the important advance was to find anions, consisting of a negatively charged atom surrounded by tightly held halogen atoms, which are just too stable to be nucleophilic. Examples include BF₄⁻, PF₆⁻, and SbF₆⁻. The first is small and tetrahedral and the others are larger and octahedral.

In these anions, the negative charge does not correspond to a lone pair of electrons (they are like BH₄⁻ in this respect) and there is no orbital high enough in energy to act as a nucleophile. By using a non-nucleophilic solvent, liquid SO₂, at low temperature, Olah was able to turn alcohols into carbocations with these counterions. This is what happens when tert-butanol is treated with SbF₅ and HF in liquid SO₂. The acid protonates the hydroxyl group, allowing it to
leave as water, while the SbF₅ grabs the fluoride ion, preventing it from acting as a nucleophile. The cation is left high and dry.

Olah's preparation of the tert-butyl cation in liquid SO₂

The proton NMR of this cation showed just one signal for the three methyl groups at 4.15 ppm, quite far downfield for C–Me groups. The ¹³C spectrum also showed downfield Me groups at 47.5 ppm, but the key evidence that the cation was formed was the shift of the central carbon atom, which came at an amazing 320.6 ppm, way downfield from anything you have met before. This carbon is very deshielded—it is positively charged and extremely electron deficient.

From Olah's work we know what the tert-butyl cation looks like by NMR, so can we use NMR to try to detect it as an intermediate in substitution reactions? If we mix t-BuBr and NaOH in an NMR tube and let the reaction run inside the NMR machine, we see no signals belonging to the cation. But this proves nothing. We would not expect a reactive intermediate to be present in any significant concentration. There is a simple reason for this. If the cation is unstable, it will react very quickly with any nucleophile around and there will never be any appreciable amount of cation in solution. Its rate of formation will be much slower than its rate of reaction.

**Alkyl substituents stabilize a carbocation**

Olah found that he could measure the spectrum of the tert-butyl cation, but he was never able to observe the methyl cation in solution. Why do those extra substituents stabilize the cationic centre?

Any charged organic intermediate is inherently unstable because of the charge. A carbocation can be formed only if it has some extra stabilization, and extra stabilization can come to the planar carbocation structure from weak donation of σ bond electrons into the empty p orbital of the cation. In the tert-butyl cation, three of these donations occur at any one time: it doesn’t matter if the C–H bonds point up or down; one C–H bond of each methyl group must be parallel to one lobe of the empty p orbital at any one time. The first diagram shows one overlap in orbital terms and the second and third diagrams, three as dotted lines.

There is nothing special about the C–H bond donating electrons into an empty orbital: a C–C bond is just as good and some bonds are better (C–Si, for example). But there must be a bond of some sort—a hydrogen atom by itself has no lone pairs and no σ bonds so it cannot stabilize a cation.

Planarity is so important to the structure of a carbocation that if a tertiary cation cannot become planar, it is not formed. A classic case is the structure in the margin, which does not react with nucleophiles either by S₅₁ or by S₅₂. It does not react by S₅₁ because the cation cannot become planar, nor by S₅₂ because the nucleophile cannot approach the carbon atom from the right direction.

In general, though, simple tertiary structures undergo efficient S₅₁ substitution reactions. With good leaving groups such as halides, substitutions can be done under neutral conditions; with less good leaving groups such as alcohols or ethers, acid catalysis is required. The following group of reactions give an idea of the types of S₅₁ reactions that work well.
An adjacent C=C π system stabilizes a carbocation: allylic and benzylic carbocations

Tertiary carbocations are more stable than primary ones, but powerful stabilization is also provided when there is genuine conjugation between the empty π orbital and adjacent π or lone pair electrons. The allyl cation has a filled (bonding) orbital containing two electrons delocalized over all three atoms and an important empty orbital with coefficients on the end atoms only. It’s this orbital that is attacked by nucleophiles. The curly arrow picture tells us the same thing.

Allylic electrophiles react well by the S_N1 mechanism because the allyl cation is relatively stable. Here’s an example of a reaction working in the opposite direction from most of those you have seen so far—we start with the alcohol and form the bromide. Treatment of cyclohexenol with HBr gives the corresponding allylic bromide.

In this case, only one compound is formed because attack at either end of the allyl cation gives the same product. But when the allylic cation is unsymmetrical this can be a nuisance as a mixture of products may be formed. It doesn’t matter which of these two butenols you treat with HBr, you get the same delocalized allylic cation.
When this cation reacts with Br\(^-\), about 80% goes to one end and 20% to the other, giving a mixture of butenyl bromides. This **regioselectivity** (where the nucleophile attacks) is determined by steric hindrance: attack is faster at the less hindered end of the allylic system.

Sometimes this ambiguity is useful. The tertiary allylic alcohol 2-methylbut-3-en-2-ol is easy to prepare and reacts well by the S\(_{\text{n}1}\) mechanism because it can form a stable carbocation that is both tertiary and allylic. The allylic carbocation intermediate is unsymmetrical and reacts only at the less substituted end to give ‘prenyl bromide’.

![2-methylbut-3-en-2-ol and 'prenyl bromide'](image)

The benzyl cation is about as stable as the allyl cation but lacks its ambiguity of reaction. Although the positive charge is delocalized around the benzene ring, to three positions in particular, the benzyl cation always reacts on the side chain so that aromaticity is preserved.

![Delocalization in the benzyl cation](image)

An exceptionally stable cation is formed when three benzene rings can help to stabilize the same positive charge. The result is the triphenylmethyl cation or, for short, the trityl cation. Trityl chloride is used to form an ether with a primary alcohol group by an S\(_{\text{n}1}\) reaction. You will notice that pyridine is used as solvent for the reaction. Pyridine (a weak base: the pK\(_a\) of its conjugate acid is 5.5—see Chapter 8) is not strong enough to remove the proton from the primary alcohol (pK\(_a\) about 15), and there would be no point in using a base strong enough to make \(\text{RCH}_2\text{O}^-\) as the nucleophile makes no difference to an S\(_{\text{n}1}\) reaction. Instead the TrCl ionizes first to trityl cation, which now captures the primary alcohol and finally pyridine is able to remove the proton from the oxonium ion. Pyridine does not catalyse the reaction; it just stops it becoming too acidic by removing the HCl formed. Pyridine is also a convenient polar organic solvent for ionic reactions.

![Trityl ether formation](image)

The table below shows the rates of solvolysis (i.e. a reaction in which the solvent acts as the nucleophile) in 50% aqueous ethanol for substituted allylic chlorides compared with benzylic chlorides and simple alkyl chlorides. The values give you an idea of the relative reactivity towards substitution of the different classes of compound. These rates are mostly S\(_{\text{n}1}\), but there will be some S\(_{\text{n}2}\) reactivity with the primary compounds.

**Carbocations are stabilized by an adjacent lone pair**

The alkyl chloride known as methyl chloromethyl ether, MeOCH₂Cl, reacts very well with alcohols to form ethers. Being a primary alkyl chloride, you might think that its reactions would follow an $S_N2$ mechanism, but in fact it has characteristic $S_N1$ reactivity. As usual, the reason for its preference for the $S_N1$ mechanism is its ability to form a stabilized carbocation. Loss of the chloride ion is assisted by the adjacent lone pair, and we can draw the resulting cation either as an oxonium ion or as a carbocation.

![Diagram of carbocations](image)

**The methoxymethyl cation**

Olah has used the methods described above to make the methoxymethyl cation in solution. Although this cation can be drawn either as an oxonium ion or as a primary carbocation, the oxonium ion structure is the more realistic. The proton NMR spectrum of the cation compared with that of the isopropyl cation (this is the best comparison we can make) shows that the protons on the CH₂ group resonate at 9.9 ppm instead of at the 13.0 ppm of the true carbocation.

If you think back to Chapter 11, you will recall that the first step in the hydrolysis of an acetal is a similar reaction, with one alkoxy group replaced by water to give a hemiacetal. We considered the mechanism for this reaction in Chapter 11 but did not then concern ourselves with a label for the first step. It is in effect an $S_N1$ substitution reaction: the decomposition of the protonated acetal to give an oxonium ion. If you compare this step with the reaction of the chloroether we have just described you will see that they are very similar in mechanism.
**A common mistake**

Don’t be tempted to shortcut this mechanism by drawing the displacement of the first molecule of methanol by water as an $S_N^2$ reaction.

An $S_N^2$ mechanism is unlikely at such a crowded carbon atom. However, the main reason why the $S_N^2$ mechanism is wrong is that the $S_N1$ mechanism is so very efficient, with a neighbouring MeO group whose lone pair can stabilize the carbocation intermediate. The $S_N2$ mechanism doesn’t get a chance.

This mechanism for the $S_N1$ replacement of one electronegative group at a carbon atom by a nucleophile where there is another electronegative group at the same carbon atom is very general. You should look for it whenever there are two atoms such as O, N, S, Cl, or Br joined to the same carbon atom. The better leaving groups (such as the halogens) need no acid catalyst but the less good ones (N, O, S) usually need acid.

We now have in the box below a complete list of the sorts of structures that normally react by the $S_N1$ mechanism rather than by the $S_N2$ mechanism.

Interactive mechanism for acetal hydrolysis

Think back to the formation and reactions of iminium ions in Chapter 11 for further examples.
A closer look at the $S_N2$ reaction

Among simple alkyl groups, methyl and primary alkyl groups always react by the $S_N2$ mechanism and never by $S_N1$. This is partly because the cations are unstable and partly because the nucleophile can push its way in easily past the hydrogen atoms.

A common way to make ethers is to treat an alkoxide anion with an alkyl halide. If the alkyl halide is a methyl compound, we can be sure that the reaction will go by the $S_N2$ mechanism. A strong base, here NaH, will be needed to form the alkoxide ion, since alcohols are weak acids ($pK_a$ about 16). Methyl iodide is a suitable electrophile.

$$\begin{align*}
\text{alcohol} & \xrightarrow{\text{NaH}} \text{alkoxide ion} & \xrightarrow{\text{methyl iodide}} \text{methyl ether} \\
\text{phenol} & \xrightarrow{\text{NaOH}} (\text{MeO})_2\text{SO}_2 & \xrightarrow{\text{dimethyl sulfate}} \text{stable sulfate anion}\end{align*}$$

With the more acidic phenols ($pK_a$ about 10), NaOH is a strong enough base and dimethyl sulfate, the dimethyl ester of sulfuric acid, is often used as the electrophile. It is worth using a strong base to make the alcohol into a better nucleophile because as we discussed on p. 331 the rate equation for an $S_N2$ reaction tells us that the strength and concentration of the nucleophile affects the rate of the reaction.

The transition state for an $S_N2$ reaction

Another way to put this would be to say that the nucleophile, the methyl group, and the leaving group are all present in the transition state for the reaction. The transition state is the highest energy point on the reaction pathway. In the case of an $S_N2$ reaction it will be the point where the new bond from the nucleophile is partly formed while the old bond to the leaving group is not yet completely broken. It will look something like this:

The dashed bonds in the transition state indicate partial bonds (the C–Nu bond is partly formed and the C–X bond partly broken) and the charges in brackets indicate substantial partial charges (about half a minus charge each in this case). Transition states are often shown in square brackets and marked with the symbol $\dagger$.

Another way to look at this situation is to consider the orbitals. The nucleophile must have lone-pair electrons, which will interact with the $\sigma^*$ orbital of the C–X bond.
In the transition state the carbon atom in the middle has a p orbital that shares one pair of electrons between the old and the new bonds. Both these pictures suggest that the transition state for an Sn2 reaction has a more or less planar carbon atom at the centre with the nucleophile and the leaving group arranged at 180° to each other. This picture can help us explain two important observations concerning the Sn2 reaction—firstly the types of structures that react efficiently, and secondly the stereochemistry of the reaction.

**Adjacent C=\(\pi\) or C=O systems increase the rate of Sn2 reactions**

We have already established that methyl and primary alkyl compounds react well by the Sn2 mechanism, while secondary alkyl compounds undergo Sn2 reactions only reluctantly. But there are other important structural features that also encourage the Sn2 mechanism. Two of these, allyl and benzyl groups, also encourage the Sn1 mechanism.

Allyl bromide reacts well with alkoxides to make ethers, and shown below is the typical Sn2 mechanism for this reaction. Also shown is the transition state for this reaction. Allyl compounds react rapidly by the Sn2 mechanism because the \(\pi\) system of the adjacent double bond can stabilize the transition state by conjugation. The p orbital at the reaction centre (shown in brown, and corresponding to the brown orbital in the diagram on p. 340) has to make two partial bonds with only two electrons—it is electron deficient, and so any additional electron density it can gather from an adjacent \(\pi\) system will stabilize the transition state and increase the rate of the reaction.

The benzyl group acts in much the same way using the \(\pi\) system of the benzene ring for conjugation with the p orbital in the transition state. Benzyl bromide reacts very well with alkoxides to make benzyl ethers.

Among the fastest of all Sn2 reactions are those where the leaving group is adjacent to a carbonyl group. With \(\alpha\)-bromo carbonyl compounds, two neighbouring carbon atoms are both powerfully electrophilic sites. Each has a low-energy empty orbital—\(\pi^*\) from C=O and \(\sigma^*\) from C–Br (this is what makes them electrophilic)—and these can combine to form a new LUMO (\(\pi^* + \sigma^*\)) lower in energy than either. Nucleophilic attack will occur easily where this new orbital has its largest coefficient, shown in orange on the diagram.

The effect of this interaction between antibonding orbitals is that each group becomes more electrophilic because of the presence of the other—the C=O group makes the C–Br bond more reactive and the Br makes the C=O group more reactive. In fact, it may well be that the nucleophile will attack the carbonyl group, but this will be reversible whereas displacement of bromide is irreversible.

There are many examples of this type of reaction. Reactions with amines go well and the aminoketone products are widely used in the synthesis of drugs.
Quantifying structural effects on $S_N2$ reactions

Some actual data may help at this point. The rates of reaction of the following alkyl chlorides with KI in acetone at 50 °C broadly illustrate the patterns of $S_N2$ reactivity we have just analysed. These are relative rates with respect to $n$-BuCl as a 'typical primary halide'. You should not take too much notice of precise figures but rather observe the trends and notice that the variations are quite large—the full range from 0.02 to 100,000 is eight powers of ten.

Contrasts between $S_N1$ and $S_N2$

You have now met the key features of both important mechanisms for substitution. You should at this stage in the chapter have a grasp of the kinetics, the nature of the intermediates and transition states, and the simple steric and electronic factors that control reactivity in $S_N1$ and $S_N2$ reaction pathways.

We are now going to look in more detail at some other aspects where there are significant contrasts between the mechanisms, either because they lead to different outcomes or because they lead to a change in reactivity towards one or the other of the two pathways.

A closer look at steric effects

We have already pointed out that having more alkyl substituents at the reaction centre makes a compound more likely to react by $S_N1$ than by $S_N2$ for two reasons: firstly they make a carbocation more stable, so favouring $S_N1$, and secondly they make it hard for a nucleophile to get close to the reaction centre in the rate-determining step, disfavouring $S_N2$. Let’s look in more detail at the transition state for the slow steps of the two reactions and see how steric hindrance affects both.
In the approach to the SN2 transition state, the carbon atom under attack gathers in another substituent and becomes (transiently) five-coordinate. The angles between the substituents decrease from tetrahedral to about 109°.

In the starting material there are four angles of about 109°. In the transition state (enclosed in square brackets and marked ‡ as usual) there are three angles of 120° and six angles of 90°, a significant increase in crowding. The larger the substituents R, the more serious this is, and the greater the increase in energy of the transition state. We can easily see the effects of steric hindrance if we compare these three structural types:

- methyl: CH₃–X: very fast SN2 reaction
- primary alkyl: RCH₂–X: fast SN2 reaction
- secondary alkyl: R₂CH–X: slow SN2 reaction.

The opposite is true of the SN1 reaction. The rate-determining step is simply the loss of the leaving group, and the transition state for this step will look something like the structure shown below—with a longer, weaker, and more polarized C–X bond than the starting material. The starting material is again tetrahedral (four angles of about 109°) and in the intermediate there are just three angles of 120°—fewer and less serious interactions. The transition state will be on the way towards the cation, and because the R groups are further apart in the transition state than in the starting material, large R groups will actually decrease the energy of the transition state relative to the starting material. SN1 reactions are therefore accelerated by alkyl substituents both for this reason and because they stabilize the cation.

Stereochemistry and substitution

Look back at the scheme we showed you for the SN2 reaction on p. 340. It shows the nucleophile attacking the carbon atom on the opposite side from the leaving group. Look carefully at the carbon atom it is attacking and you see that its substituents end up turning inside out as the reaction goes along, just like an umbrella in a high wind. If the carbon atom under attack is a stereogenic centre (Chapter 14), the result will be inversion of configuration. Something very different happens in the SN1 reaction, and we will now illustrate the difference with a simple sequence of reactions.

Starting with the optically active secondary alcohol sec-butanol (or butan-2-ol, but we want to emphasize that it is secondary), the secondary cation can be made by the method described on p. 338. Quenching this cation with water regenerates the alcohol but without any optical
activity. Water must attack the two faces of the planar cation with exactly equal probability: the product is an exactly 50:50 mixture of (S)-butanol and (R)-butanol. It is racemic.

Alternatively, we can first make the hydroxyl group into a good enough leaving group to take part in an $S_N2$ reaction. The leaving group we shall use, a sulfonate ester, will be introduced to you in a few pages’ time, but for now you just need to accept that nucleophilic attack of the OH group on a sulfonyl chloride in pyridine solution gives the sulfonate ester shown below in orange: no bonds have been formed or broken at the chiral carbon atom, which still has (S) stereochemistry.

Now we can carry out an $S_N2$ reaction on the sulfonate with an acetate anion. A tetra-alkyl ammonium salt is used in the solvent DMF to avoid solvating the acetate, making it as powerful a nucleophile as possible and getting a clean $S_N2$ reaction. This is the key step and we don’t want any doubt about the outcome. The sulfonate is an excellent leaving group—the charge is delocalized across all three oxygen atoms.

The product sec-butyl acetate is optically active and we can measure its optical rotation. But this tells us nothing. Unless we know the true rotation for pure sec-butyl acetate, we don’t yet know whether it is optically pure nor even whether it really is inverted. We expect it to have (R) stereochemistry, but we can easily find out for sure. All we have to do is to hydrolyse the ester and get the original alcohol back again. We know the true rotation of the alcohol—it was our starting material—and we know that ester hydrolysis (Chapter 10) proceeds by attack at the carbonyl carbon—it can’t affect the stereochemistry of the chiral centre.

Now we really know where we are. This new sample of sec-butanol has the same rotation as the original sample, but with the opposite sign. It is (–)-(R)-sec-butanol. It is optically pure and inverted. Somewhere in this sequence there has been an inversion, and we know it wasn’t in the formation of the sulfonate or the hydrolysis of the acetate as no bonds are formed or broken at the stereogenic centre in these steps. It must have been in the $S_N2$ reaction itself.

- An $S_N2$ reaction goes with inversion of configuration at the carbon atom under attack but an $S_N1$ reaction generally goes with racemization.

The effect of solvent

Why was the $S_N2$ reaction we have just shown you carried out in DMF? You will generally find $S_N2$ reactions are carried out in aprotic, and often less polar, solvents. $S_N1$ reactions are
typically carried out in polar, protic solvents. A common solvent for an S\textsubscript{N2} reaction is acetone—just polar enough to dissolve the ionic reagents, but not as polar as, say, acetic acid, a common solvent for the S\textsubscript{N1} reaction.

It is fairly obvious why the S\textsubscript{N1} reaction needs a polar solvent: the rate-determining step involves the formation of ions (usually a negatively charged leaving group and a positively charged carbocation) and the rate of this process will be increased by a polar solvent that can solvate these ions. More precisely, the transition state is more polar than the starting materials (note the charges in brackets in the scheme above) and so is stabilized by the polar solvent. Hence solvents like water or carboxylic acids (RCO\textsubscript{2}H) are ideal.

It is less obvious why a less polar solvent is better for the S\textsubscript{N2} reaction. The most common S\textsubscript{N2} reactions use an anion as the nucleophile. The transition state is then less polar than the localized anion as the charge is spread between two atoms. Here’s an example: the formation of an alkyl iodide from an alkyl bromide. Acetone fails to solvate the iodide well, making it more reactive; the transition state is less in need of solvation, so overall the reaction is faster.

[Diagram showing the mechanism of S\textsubscript{N1} and S\textsubscript{N2} reactions]

DMF and DMSO, the polar aprotic solvents we discussed in Chapter 12 (p. 255) are also good solvents for S\textsubscript{N2} reactions because they dissolve ionic compounds well but fail to solvate anions well, making them more reactive. The choice of Bu\textsubscript{4}N\textsuperscript{+}—a large, non-coordinating cation—as the counterion for the reaction on p. 344 was also made with this in mind.

**Quantifying the rates of S\textsubscript{N1} and S\textsubscript{N2} reactions**

The data below illustrate the effect of structure on the rates of S\textsubscript{N1} and S\textsubscript{N2} reactions. The green curve on the graph shows the rates (k\textsubscript{1}) of an S\textsubscript{N1} reaction: the conversion of alkyl bromides to alkyl formate esters in formic acid at 100 °C. Formic acid is a polar solvent and a weak nucleophile: perfect for an S\textsubscript{N1} reaction. The red curve shows the rates of displacement of Br\textsuperscript{−} by radioactive ^82Br\textsuperscript{−} in acetone at 25 °C. Acetone solvent and the good nucleophile Br\textsuperscript{−} favour S\textsubscript{N2}. The rates (k\textsubscript{2}) are multiplied by 10\textsuperscript{5} to bring both curves onto the same graph.

Both curves are plotted on a log scale, the log\textsubscript{10} of the actual rate being used on the y-axis. The x-axis has no real significance; it just shows the four points corresponding to the four basic structures: MeBr, Me\textsubscript{2}CHBr, Me\textsubscript{2}CH\textsubscript{2}Br, and Me\textsubscript{3}CB\textsubscript{r}.

[Graph showing the rates of S\textsubscript{N1} and S\textsubscript{N2} reactions for simple alkyl bromides]
The values are also summarized in the table below, which gives the relative rates compared with that of the secondary halide, i-PrBr, set at 1.0 for each reaction.

Although the reactions were chosen to give as much \( \text{S}_1 \) reaction as possible in one case and as much \( \text{S}_2 \) reaction as possible in the other, of course you will understand that we cannot prevent the molecules doing the ‘wrong’ reaction! The values for the ‘\( \text{S}_1 \)’ reaction of MeBr and MeCH₂Br are actually the low rates of \( \text{S}_2 \) displacement of the bromide ion by the weak nucleophile HCO₂H, while the ‘\( \text{S}_2 \)’ rate for t-BuBr may be the very small rate of ionization of t-BuBr in acetone.

**A closer look at electronic effects**

We mentioned above that adjacent \( \pi \) systems increase the rate of the \( \text{S}_2 \) reaction by stabilizing the transition state, and likewise increase the rate of \( \text{S}_1 \) reactions by stabilizing the carbocation. The effect on the \( \text{S}_2 \) reaction applies to both C=O (electron-rich) and C=O (electron-deficient) \( \pi \) systems, but only C=C \( \pi \) systems increase the rate of \( \text{S}_1 \) reactions. Adjacent C=O groups in fact significantly decrease the reactivity of alkyl halides towards \( \text{S}_1 \) reactions because the electron-withdrawing effect of the carbonyl group greatly destabilizes the carbocation.

Electron-withdrawing or -donating groups can also tip finely balanced cases from one mechanism to another. For example, benzylic compounds react well by either \( \text{S}_1 \) or \( \text{S}_2 \), and a change of solvent, as just discussed, might switch them from one mechanism to another. Alternatively, a benzylic compound that has a well-placed electron-donating group able to stabilize the cation will also favour the \( \text{S}_1 \) mechanism. Thus 4-methoxybenzyl chloride reacts by \( \text{S}_1 \) for this reason: here we show the methoxy group stabilizing the cation intermediate by assisting departure of the chloride.

![Electron donation favours the \( \text{S}_1 \) mechanism](image)

On the other hand, an electron-withdrawing group, such as a nitro group, within the benzylic compound will decrease the rate of the \( \text{S}_1 \) reaction and allow the \( \text{S}_2 \) mechanism to take over.

![Electron withdrawal disfavours the \( \text{S}_1 \) mechanism](image)

Rate measurements for benzylic chlorides illustrate the importance of this effect. We can force them all to react by \( \text{S}_1 \) by using methanol as the solvent (methanol is a poor nucleophile and a polar solvent; both disfavour \( \text{S}_2 \)). Comparing with the rate of substitution of benzyl chloride itself, PhCH₂Cl, 4-methoxybenzyl chloride reacts with methanol about 2500 times faster and the 4-nitrobenzyl chloride about 3000 times more slowly.
Summary of structural variations and nucleophilic substitution

We are now in a position to summarize the structural effects on both mechanisms we have been discussing over the last few pages. The table lists the structural types and rates each reaction qualitatively.

\[ \text{SN}_1 \text{ mechanism?} \]
good   good   good   bad   bad

\[ \text{SN}_2 \text{ mechanism?} \]
good   good   okay but \(\text{SN}_1\) better   excellent   possible

We have considered the important effects of the basic carbon skeleton and of solvent on the course of \(\text{SN}_1\) and \(\text{SN}_2\) reactions and we shall now look at two final structural factors: the nucleophile and the leaving group. We shall tackle the leaving group first because it plays an important role in both \(\text{SN}_1\) and \(\text{SN}_2\) reactions.

The leaving group in \(\text{SN}_1\) and \(\text{SN}_2\) reactions

The leaving group is important in both \(\text{SN}_1\) and \(\text{SN}_2\) reactions because departure of the leaving group is involved in the rate-determining step of both mechanisms.

So far you have mostly seen halides and water (from protonated alcohols) as leaving groups. Leaving groups involving halides or oxygen atoms are by far the most important, and now we need to establish the principles that make for good and bad leaving groups. As a chemist, we want leaving groups to have some staying power, so that our compounds are not too unstable, but we also don’t want them to outstay their welcome—they must have just the right level of reactivity.

Halides as leaving groups

With halide leaving groups two main factors are at work: the strength of the C–halide bond and the stability of the halide ion. The strengths of the C–X bonds can be measured easily, but how can we measure anion stability? One way, which you met in Chapter 8, was to use the \(pK_a\) values of the acids \(HX\). \(pK_a\) quantifies the stability of an anion relative to its conjugate acid. We want to know about the stability of an anion relative to that anion bonded to C, not H, but \(pK_a\) will do as a guide.
The table in the margin shows both bond strengths and $\mathrm{pK_a}$. It is clearly easiest to break a C–I bond and most difficult to break a C–F bond. Iodide sounds like the best leaving group. We get the same message from the $\mathrm{pK_a}$ values: HI is the strongest acid, so it must ionize easily to $\mathrm{H}^+$ and I$. This result is quite correct—iodide is an excellent leaving group and fluoride a very bad one, with the other halogens in between.

**Nucleophilic substitutions on alcohols: how to get an OH group to leave**

Now what about leaving groups joined to the carbon atom by a C–O bond? There are many of these but the most important are OH itself, the carboxylic esters, and the sulfonate esters. First we must make one thing clear: alcohols themselves do not react with nucleophiles. In other words, $\mathrm{OH}^-$ is never a leaving group. Why not? For a start hydroxide ion is very basic, and if the nucleophile were strong enough to displace hydroxide ion it would be more than strong enough to remove the proton from the alcohol.

$$\text{Nu}^- \text{O}^+ \text{H}^+ \text{H}^+ \text{Nu}^-$$

But we do want to use alcohols in nucleophilic substitution reactions because they are easily made (by the reactions in Chapter 9, for example). The simplest solution is to protonate the OH group with strong acid. This will work only if the nucleophile is compatible with strong acid, but many are. The preparation of $t$-BuCl from $t$-BuOH simply by shaking it with concentrated HCl is a good example. This is obviously an $\mathrm{S_N}1$ reaction with the $t$-butyl cation as intermediate.

Similar methods can be used to make secondary alkyl bromides with HBr alone and primary alkyl bromides using a mixture of HBr and $\text{H}_2\text{SO}_4$.

The second of these two reactions must be $\mathrm{S_N}2$, with substitution of the protonated hydroxyl group by bromide.

Another way to approach the substitution of OH is to make it a better leaving group by combination with an element that forms very strong bonds to oxygen. The most popular choices are phosphorus and sulfur. Making primary alkyl bromides with PBr$_3$ usually works well. The phosphorus reagent is first attacked by the OH group (an $\mathrm{S_N}2$ reaction at phosphorus) and the displacement of an oxyanion bonded to phosphorus is now a good reaction because of the anion stabilization by phosphorus.
Sulfonate esters—tosylates and mesylates—from alcohols

The most widely used way of making a hydroxyl group into a good leaving group is to make it into a sulfonate ester. Primary and secondary alcohols are easily converted to sulfonate esters by treating with sulfonyl chlorides and base. The sulfonate esters are often crystalline, and are so widely used that they have been given trivial names—**tosylates** for $p$-toluenesulfonates and **mesylates** for methanesulfonates—and the functional groups have been allocated the ‘organic element’ symbols $Ts$ and $Ms$.

**Tosylates** ($p$-toluenesulfonates) are made by treating alcohols with $p$-toluenesulfonyl chloride (or tosyl chloride) in the presence of pyridine. A similar reaction (but with a different mechanism, which we will discuss in Chapter 17) with methanesulfonyl chloride (mesyl chloride) gives a mesylate (methanesulfonate).

![Chemical structures](image1)

Sulfonic acids $RSO_3H$ are strong acids ($pK_a$ around 0) and so any sulfonate $RSO_3^-$ is a good leaving group: tosylates and mesylates can be displaced by almost anything. As you saw in Chapter 8, the lithium derivative of an alkyne can be prepared by deprotonation with the very strong base butyllithium. In the example below, the tosyl derivative of a primary alcohol reacts with this lithium derivative in an $S_N2$ reaction. Note that the tosylate leaving group is represented as $TsO^-$ (not $Ts^-$).

![Chemical structures](image2)

On p. 344 you saw a tosylate (we just called it a sulfonate ester then) being displaced by acetate in an $S_N2$ reaction. Acetate is not a very good nucleophile, and it is a testament to the power of the sulfonate esters that they are willing to act as leaving groups even with acetate, which is usually too weak to react by $S_N2$.

**Substituting alcohols with the Mitsunobu reaction**

Rather than use two steps to convert the OH group first to a sulfonate ester, and then displace it, it is possible to use a method that allows us to put an alcohol straight into a reaction mixture and get an $S_N2$ product in one operation. This is the Mitsunobu reaction. In this reaction, the alcohol becomes the electrophile, the nucleophile is usually relatively weak (the conjugate base of a carboxylic acid, for example), and there are two other reagents.

![Chemical structures](image3)

---

**Oyo Mitsunobu** (1934–2003) worked at the Aoyama Gakuin University in Tokyo. Western chemists often misspell his name: make sure you don’t!

---

349

THE LEAVING GROUP IN $S_N1$ AND $S_N2$ REACTIONS
One of these reagents, Ph₃P, triphenylphosphine, is the simple phosphine you met in Chapter 11. Phosphines are nucleophilic, but not basic like amines. The other reagent deserves more comment. Its full name is diethyl azodicarboxylate, or DEAD.

So how does the Mitsunobu reaction work? It’s a long mechanism, but don’t be discouraged: there is a logic to each step and we will guide you through it gently. The first stage involves neither the alcohol nor the added nucleophile. The phosphine adds to the weak N=N π bond to give an anion stabilized by one of the ester groups.

You will note that the nucleophile has been added as its conjugate acid ‘HNu’—often this might be a carboxylic acid, for example benzoic acid. The anion produced by this first stage is basic enough to remove a proton from this acid, generating Nu⁻ ready for reaction.

Oxygen and phosphorus have a strong affinity, as we saw in the conversion of alcohols to bromides with PBr₃ (p. 348) and in the Wittig reaction (Chapter 11, pp. 237–8), and the positively charged phosphorus is now attacked by the alcohol, displacing a second nitrogen anion in an SN₂ reaction at phosphorus. The nitrogen anion generated in this step is stabilized by conjugation with the ester, but rapidly removes the proton from the alcohol to give an electrophilic R–O–PPh₃⁺ species and a by-product, the reduced form of DEAD.

Finally, the anion of the nucleophile can now attack this phosphorus derivative of the alcohol in a normal SN₂ reaction at carbon with the phosphine oxide as the leaving group. We have arrived at the products.

The whole process takes place in one operation. The four reagents are all added to one flask and the products are the phosphine oxide, the reduced azo diester with two NH bonds replacing the N=N double bond, and the product of an SN₂ reaction on the alcohol. Another way to look at this reaction is that a molecule of water must formally be lost: OH must be removed from the alcohol and H from the nucleophile. These atoms end up in very stable molecules—the P=O and N–H bonds are strong where the N=N bond was weak, compensating for the sacrifice of the strong C–O bond in the starting alcohol.

If this is all correct, then the vital SN₂ step should lead to inversion as it always does in SN₂ reactions. This turns out to be one of the great strengths of the Mitsunobu reaction—it is a
reliable way to replace OH by a nucleophile with inversion of configuration. The most dramatic example is probably the formation of esters from secondary alcohols with inversion. Normal ester formation leads to retention as the C–O bond of the alcohol is not broken: compare these two reactions and note the destination of the coloured oxygen (and hydrogen) atoms.

ester formation from a secondary alcohol with inversion by the Mitsunobu reaction

\[
\text{R} \text{OH} + \text{PhCl} \xrightarrow{\text{Ph}_3\text{P}} \text{R} \text{O} \text{Ph} + \text{Ph}_3\text{P}=\text{O}
\]

ester formation from a secondary alcohol with retention

\[
\text{R} \text{OH} + \text{Cl} \xrightarrow{\text{EtO}_2\text{C}=\text{N}} \text{R} \text{O} \text{Ph}
\]

**Ethers as electrophiles**

Ethers are stable molecules that do not react with nucleophiles: THF and Et₂O are widely used as solvents for this reason. To make them react, we need to make the oxygen positively charged so that it can accept electrons more readily, and we also need to use a very good nucleophile. A good way of doing both is to treat with HBr or HI, which protonate the oxygen. Iodide and bromide are excellent nucleophiles in S₂ reactions (see below), and attack will occur preferentially at the carbon atom more susceptible to S₂ reactions (usually the less hindered one). Aryl alkyl ethers cleave only on the alkyl side—you cannot get attack through the benzene ring.

\[
\text{phenyl methyl ether (anisole, or methoxybenzene)} \xrightarrow{\text{HI}} \text{MeI} \rightarrow \text{OH}
\]

So far we have used only protic acids to help oxygen atoms to leave. But Lewis acids—species other than H⁺ that also have an empty orbital capable of accepting a lone pair—work well too, and the cleavage of aryl alkyl ethers with BBr₃ is a good example. Trivalent boron compounds have an empty p orbital so they are very electrophilic and prefer to attack oxygen. The resulting oxonium ion can be attacked by Br⁻ in an S₂ reaction.

\[
\text{BBr₃ acts as a Lewis acid—empty p orbital accepts a lone pair of electrons}
\]

**Epoxides as electrophiles**

One family of ethers reacts in nucleophilic substitution even without protic or Lewis acids. They are the three-membered cyclic ethers called epoxides (or oxiranes). The leaving group is genuinely an alkoxide anion RO⁻, so obviously some special feature must be present in these ethers making them unstable. This feature is ring strain, which comes from the angle between the bonds in the three-membered ring that has to be 60° instead of the ideal tetrahedral angle of 109°. You could subtract these numbers and say that there is ‘49° of strain’ at each carbon atom, making about 150° of strain in the molecule. This is a lot: the molecule would be much...
more stable if the strain were released by opening up to restore the ideal tetrahedral angle at all atoms. This can be done by one nucleophilic attack.

Epoxides react cleanly with amines to give amino alcohols. We have not so far featured amines as nucleophiles because their reactions with alkyl halides are often bedevilled by overreaction (see the next section), but with epoxides they give good results.

It is easy to see that inversion occurs in these \( S_N2 \) reactions when the epoxide is attached to (or ‘fused with’) another ring. With this five-membered ring nucleophilic attack with inversion gives the \( \text{trans} \) product. As the epoxide in the starting material is \( \text{up} \), attack has to come from underneath. The new C–N bond is \( \text{down} \) and inversion has occurred.

The nucleophile in \( S_N1 \) reactions

We established earlier that in an \( S_N1 \) reaction the nucleophile is not important with regard to \textit{rate}. The rate-determining step of the reaction is loss of the leaving group, so good and bad nucleophiles all give products. We don’t need to deprotonate the nucleophile to make it more reactive (water and hydroxide work just as well as each other) and this means that \( S_N1 \) reactions are often carried out under acidic conditions, to assist departure of a leaving group.

Compare, for example, these typical conditions used to make a methyl ether and a \textit{tert}-butyl ether. The methyl ether is made, as you saw on p. 340, using methyl iodide in an \( S_N2 \) reaction. It needs a good nucleophile, so the alcohol is deprotonated to make an alkoxide with sodium hydride in DMF, which, as you saw on p. 345, is a good solvent for \( S_N2 \) reactions. The \textit{tert}-butyl ether on the other hand is made simply by stirring the alcohol with \textit{tert}-butanol and a little acid. No base is needed, and the reaction proceeds rapidly to give the \textit{tert}-butyl ether.
A very bad nucleophile in a good S\textsubscript{N}1 reaction: the Ritter reaction

An interesting result of the unimportance of the nucleophile to the rate (and therefore the usefulness) of an S\textsubscript{N}1 reaction is that very poor nucleophiles indeed may react in the absence of anything better. Nitriles, for example, are very poorly basic and nucleophilic because the lone pair of electrons on the nitrogen atom is in a low-energy sp orbital. However, if t-butanol is dissolved in a nitrile as solvent and strong acid is added, a reaction does take place. The acid does not protonate the nitrile, but does protonate the alcohol to produce the t-butyl cation in the usual first step of an S\textsubscript{N}1 reaction. This cation is reactive enough to combine with even such a weak nucleophile as the nitrile.

\[
\begin{align*}
&\text{OH} \\ &\text{H}^+ \\ &\text{OH}_2 \\ &\text{N} \equiv \text{R} \\ &\text{t-butyl cation} \\ &\text{OH}_2
\end{align*}
\]

The resulting cation is captured by the water molecule released in the first step and an exchange of protons leads to a secondary amide. The overall process is called the Ritter reaction and it is one of the few reliable ways to make a C–N bond to a tertiary centre.

\[
\begin{align*}
&\text{N} \equiv \text{R} \\ &\text{OH}_2 \\ &\text{new C–N bond}
\end{align*}
\]

The nucleophile in the S\textsubscript{N}2 reaction

In an S\textsubscript{N}2 reaction, a good nucleophile is essential. We finish this chapter with a survey of effective choices for forming new bonds to sp\textsuperscript{3} by S\textsubscript{N}2 reactions, and a description of the factors that determine how good a nucleophile will be.

Nitrogen nucleophiles: a problem and a solution

Amines are good nucleophiles, but reactions between ammonia and alkyl halides rarely lead cleanly to single products. The problem is that the product of the substitution is at least as nucleophilic as the starting material, so it competes for reaction with the alkyl halide.

\[
\begin{align*}
\text{XR} &\rightarrow \text{RN} \equiv \text{H} \\ \text{NH}_3 &\rightarrow \text{RN} \equiv \text{H} + \text{NH}_4^+ \\ \text{primary amine formed} &\text{in reaction mixture} \\ \text{NH}_3 &\rightarrow \text{RN} \equiv \text{H} + \text{RNH}_3^+ \\ \text{secondary amine formed} &\text{in reaction mixture}
\end{align*}
\]

Even this is not all! The alkylation steps keep going, forming the secondary and tertiary amines, and stopping only when the non-nucleophilic tetra-alkylammonium ion R\textsubscript{4}N\textsuperscript{+} is formed. The problem is that the extra alkyl groups push more and more electron density onto N, making each product more reactive than the previous. The quaternary ammonium salt could probably be made cleanly if a large excess of alkyl halide RX is used, but other more controlled methods are needed for the synthesis of primary, secondary, and tertiary amines.

One solution for primary amines is to replace ammonia with azide ion N\textsubscript{3}⁻. This linear triatomic species, nucleophilic at both ends, is a slender rod of electrons able to insert itself into almost any electrophilic site. It is available as the water-soluble sodium salt NaN\textsubscript{3}.
Azide reacts only once with alkyl halides because the product, an alkyl azide, is no longer nucleophilic. However, rarely is the azide product required: it is usually reduced to a primary amine by catalytic hydrogenation (H₂ over a Pd catalyst—see Chapter 23), LiAlH₄, or triphenylphosphine.

$$RX + NaN_3 \rightarrow RN_3 \rightarrow RNH_2$$

Azides react with epoxides too. This epoxide is one diastereoisomer (trans) but racemic and the symbol (±) under each structure reminds you of this (Chapter 14). Azide attacks at either end of the three-membered ring (the two ends are the same) to give the hydroxy-azide. The reaction is carried out in a mixture of water and an organic solvent with ammonium chloride as buffer to provide a proton for the intermediate. Triphenylphosphine in water is used for reduction to the primary amine.

The mechanism of the reduction of azides by triphenylphosphine can be found on p. 1176.

**Sulfur nucleophiles are better than oxygen nucleophiles in Sₙ2 reactions**

Thiolate anions RS⁻ make excellent nucleophiles in Sₙ2 reactions on alkyl halides. It is enough to combine the thiol, sodium hydroxide, and the alkyl halide to get a good yield of the sulfide.

$$PhSH + NaOH + \text{ } n\text{-}BuBr \rightarrow PhSBu + NaBr$$

Thiols are more acidic than water (pKₐ of RSH is typically 9–10, pKₐ of PhSH is 6.4, pKₐ of H₂O is 15.7) and rapid proton transfer from sulfur to oxygen gives the thiolate anion that acts as a nucleophile in the Sₙ2 reaction.

But how do you make a thiol in the first place? The obvious way to make aliphatic thiols would be by an Sₙ2 reaction using NaSH on the alkyl halide.

This works well but, unfortunately, the product easily exchanges a proton and the reaction normally produces the symmetrical sulfide—this should remind you of what happened with amines!
The solution is to use the anion of thioacetic acid, usually the potassium salt. This reacts cleanly through the more nucleophilic sulfur atom and the resulting ester can be hydrolysed in base to liberate the thiol.

Effectiveness of different nucleophiles in the $S_N2$ reaction

In Chapter 10 we pointed out that basicity is nucleophilicity towards protons. At that stage we said that nucleophilicity towards the carbonyl group parallels basicity almost exactly. We are able to use $pK_a$ as a guide to the effectiveness of nucleophilic substitution reactions at the carbonyl group.

During this chapter you have had various hints that nucleophilicity towards saturated carbon is not so straightforward. Now we must look at this question seriously and try to give you helpful guidelines.

1. If the atom that is forming the new bond to carbon is the same over a range of nucleophiles—it might be oxygen, for example, and the nucleophiles might be HO$^-$, PhO$^-$, AcO$^-$, and TsO$^-$—then nucleophilicity does parallel basicity. The anions of the weakest acids are the best nucleophiles. The order for the nucleophiles we have just mentioned will be: HO$^-$ > PhO$^-$ > AcO$^-$ > TsO$^-$.

   The actual values for the rates of attack of the various nucleophiles on MeBr in EtOH relative to the rate of reaction with water (= 1) are given in the table below.

<table>
<thead>
<tr>
<th>Nucleophile $X^-$</th>
<th>$pK_a$ of HX</th>
<th>Relative rate</th>
</tr>
</thead>
<tbody>
<tr>
<td>HO$^-$</td>
<td>15.7</td>
<td>$1.2 \times 10^4$</td>
</tr>
<tr>
<td>PhO$^-$</td>
<td>10.0</td>
<td>$2.0 \times 10^3$</td>
</tr>
<tr>

<td>H$_2$O</td>
<td>$-1.7$</td>
<td>1.0</td>
</tr>
<tr>
<td>ClO$_4^-$</td>
<td>$-10$</td>
<td>0</td>
</tr>
</tbody>
</table>

2. If the atoms that are forming the new bond to carbon are not the same over the range of nucleophiles we are considering, then another factor is important. In the very last examples we have been discussing we have emphasized that RS$^-$ is an excellent nucleophile for saturated carbon. Let us put that another way: RS$^-$ is a better nucleophile for saturated carbon than RO$^-$, even though RO$^-$ is more basic than RS$^-$ (see table below).

<table>
<thead>
<tr>

<tr>
<td>PhO$^-$</td>
<td>10.0</td>
<td>$2.0 \times 10^3$</td>
</tr>
</tbody>
</table>

Sulfur is plainly a better nucleophile than oxygen for saturated carbon. Why should this be? As we discussed back in Chapter 5, there are two main factors controlling bimolecular reactions: (1) electrostatic attraction (simple attraction of opposite charges or partial charges) and (2) bonding interactions between the HOMO of the nucleophile and the LUMO of the electrophile.
A proton is, of course, positively charged, so electrostatic attraction is the more important factor in nucleophilicity towards H\(^+\), or pK\(_a\). The carbonyl group too has a substantial positive charge on the carbon atom, arising from the uneven distribution of electrons in the C=O π bond, and reactions of nucleophiles with carbonyl groups are also heavily influenced by electrostatic attraction, with HOMO–LUMO interactions playing a smaller role.

When it comes to saturated carbon atoms carrying leaving groups, polarization is typically much less important. There is, of course, some polarity in the bond between a saturated carbon atom and, say, a bromine atom, but the electronegativity difference between C and Br is less than half that between C and O. In alkyl iodides, one of the best classes of electrophiles in S\(_{N2}\) reactions, there is in fact almost no dipole at all—the electronegativity of C is 2.55 and that of I is 2.66.

Electrostatic attraction is often unimportant in S\(_{N2}\) reactions. What does matter is the strength of the HOMO–LUMO interaction. In a nucleophilic attack on the carbonyl group, the nucleophile adds in to the low-energy π* orbital. In a nucleophilic attack on a saturated carbon atom, the nucleophile must donate its electrons to the σ* orbital of the C–X bond, as illustrated in the margin for an alkyl bromide reacting with the non-bonding lone pair of a nucleophile.

σ* antibonding orbitals are, of course, higher in energy than non-bonding lone pairs, but the higher the energy of the nucleophile’s lone pair, the better the overlap. The 3sp\(^3\) lone-pair electrons of sulfur overlap better with the high-energy σ* orbital of the C–X bond than do the lower energy 2sp\(^3\) lone-pair electrons on oxygen because the higher energy of the sulfur electrons brings them closer in energy to the C–X σ* orbital. The conclusion is that nucleophiles from lower down the periodic table are more effective in S\(_{N2}\) reactions than those from the top rows.

Hard and soft nucleophiles

The fact that some nucleophiles, like $R_3P^-$ and $RS^-$, react very fast at saturated C atoms (they have high-energy lone pairs), but very poorly at C=O groups (they are either uncharged or have charge spread diffusely over large orbitals) gives them a different type of character from strongly basic nucleophiles like $HO^-$ that attack C=O groups rapidly. We call nucleophiles that react well at saturated carbon soft nucleophiles; those that are more basic and react well with carbonyl groups are referred to as hard nucleophiles. These are useful and evocative terms because the soft nucleophiles are indeed rather large and flabby with diffuse high-energy electrons while the hard nucleophiles are small and spiky with closely held electrons and high charge density.

When we say ‘hard’ (nucleophile or electrophile) we refer to species whose reactions are dominated by electrostatic attraction and when we say ‘soft’ (nucleophile or electrophile) we refer to species whose reactions are dominated by HOMO–LUMO interactions.

Nucleophiles and leaving groups compared

In Chapter 10 we explained that, in a nucleophilic attack on the carbonyl group, a good nucleophile is a bad leaving group and vice versa. We set you the challenge of predicting which way the following reaction would go.

\[
\text{ester} \quad \text{NH}_3 \quad ? \quad \text{MeOH} \quad \text{amide ester} \\
\text{OMe} \quad \text{NH}_2 \quad \text{MeOH} \quad \text{NH}_2 \quad \text{amide}
\]

You should by now understand well that the reaction goes from ester to amide rather than the other way round, because NH$_3$ is a better nucleophile than MeOH and NH$_2^-$ is a worse leaving group than MeO$^-$.

The $S_2$ reaction is different: some of the best nucleophiles are also the best leaving groups. The most important examples of this are bromide and iodide. As the table on p. 356 showed, iodide ion is one of the best nucleophiles towards saturated carbon because it is at the bottom of its group in the periodic table and its lone-pair electrons are very high in energy. Alkyl iodides are readily formed from alkyl chlorides or tosylates. Here are two examples. The first is assisted by the solvent, acetone, which allows NaCl to precipitate and drives the reaction forward.
The second example is from the preparation of a phosphonium salt used in a synthesis of terpenes. An unsaturated primary alcohol was first made into its tosylate, the tosylate was converted into the iodide, and the iodide into the phosphonium salt.

\[
\text{OH} \quad \xrightarrow{\text{TsCl, pyridine}} \quad \text{OTs} \quad \xrightarrow{\text{I, benzene}} \quad \phi \text{Ph}^3 \quad \xrightarrow{\text{acetone}} \quad \text{phosphonium salt}
\]

But why this roundabout route via the iodide? The answer is that as well as being an excellent nucleophile, iodide is such a good leaving group that alkyl iodides are often used as intermediates to encourage substitution with other nucleophiles. Yields are often higher if the alkyl iodide is prepared than if the eventual nucleophile is reacted directly with the alkyl tosylate or chloride.

However, iodine is expensive, and a way round that problem is to use a catalytic amount of iodide. The phosphonium salt below is formed slowly from benzyl bromide but the addition of a small amount of LiI speeds up the reaction considerably.

\[
\text{Br} \quad \xrightarrow{\text{Ph}^3 \text{P}, \text{reflux in xylene}} \quad \text{reaction takes days}
\]

\[
\text{Br} \quad \xrightarrow{\text{Ph}^3 \text{P}, \text{catalytic LiI, reflux in xylene}} \quad \text{reaction complete in 2 hours}
\]

The iodide reacts both as a better nucleophile than Ph\(^3\)P and then as a better leaving group than Br\(^-\). Each iodide ion goes round the cycle many times as a nucleophilic catalyst.

Looking forward: elimination and rearrangement reactions

Simple nucleophilic substitutions at saturated carbon atoms are fundamental reactions found wherever organic chemistry is practised. They are used in industry on an enormous scale and in pharmaceutical laboratories to make important drugs. They are worth studying for their importance and relevance.

There is another side to this simple picture. These were among the first reactions whose mechanisms were thoroughly investigated by Ingold in the 1930s and since then they have probably been studied more than any other reactions. All our understanding of organic mechanisms begins with \(S_N1\) and \(S_N2\) reactions, and you need to understand these basic mechanisms properly.

The carbocations you met in this chapter are reactive intermediates not only in \(S_N1\) substitutions but in other reactions too. One of the most convincing pieces of evidence for their formation is that they undergo reactions other than simple addition to nucleophiles. For example, the carbon skeleton of the cation may rearrange, as we will discuss in Chapter 36.
Another common fate of cations, and something that may also happen instead of an intended $S_N1$ or $S_N2$ reaction, is elimination. Here an alkene is formed by the nucleophile acting as a base to remove HX instead of adding to the molecule.

You will meet elimination reactions in the next chapter but one (17) after some further exploration of stereochemistry.

- How conformation, and the alignment of atoms, can affect elimination reactions ch17
- How NMR spectroscopy backs up what we have said in this chapter ch31
- How the conformation of molecules dictates how they react, e.g. from which direction they will be attacked by reagents ch32 & ch33
- How the alignment of bonds can allow groups in molecules to move around (rearrangement reactions) or allow C–C bonds to break (fragmentation reactions) ch36
- How the alignment of orbitals controls reactivity (stereoelectronics) ch31
- The accurate drawing of rings as transition states is necessary ch32, ch34, & ch35

Bond rotation allows chains of atoms to adopt a number of conformations

Several chapters of this book have considered how to find out the structure of molecules. We have seen X-ray crystallography pictures, which reveal exactly where the atoms are in crystals; we have looked at IR spectroscopy, which gives us information about the bonds in the molecule, and at NMR spectroscopy, which gives us information about the atoms themselves and how they are joined up. Up to now, we have mainly been interested in determining which atoms are bonded to which other atoms and also the shapes of small localized groups of atoms. For example, a methyl group has three hydrogen atoms bonded to one carbon atom and the atoms around this carbon are located at the corners of a tetrahedron; a ketone consists of a carbon atom bonded to two other carbon atoms and doubly bonded to an oxygen atom, with all these atoms in the same plane.

But, on a slightly larger scale, shape is not usually so well defined. Rotation is possible about single bonds and this rotation means that, while the localized arrangement of atoms stays the same (every saturated carbon atom is still always tetrahedral), the molecule as a whole can adopt a number of different shapes. Shown on the next page are several snapshot views of one molecule—it happens to be a pheromone used by pea moths to attract a mate. Although the structures look dissimilar, they differ from one another only by rotation about one or more single bonds. Whilst the overall shapes differ, the localized structure is still the
same: tetrahedral sp³ carbons; trigonal planar sp² carbons. Notice another point too, which we will pick up on later: the arrangement about the double bond always remains the same because double bonds can’t rotate.

At room temperature in solution, all the single bonds in the molecule are constantly rotating—the chances that two molecules will have exactly the same shape at any one time are quite small.

Yet, even though no two molecules have exactly the same shape at any one time, they are still all the same chemical compound—they have all the same atoms attached in the same way. We call the different shapes of molecules of the same compound different conformations.

**Conformation and configuration**

To get from one conformation to another, we can rotate about as many single bonds as we like. The one thing we can’t do though is to break any bonds. This is why we can’t rotate about a double bond—to do so we would need to break the π bond. Below are some pairs of structures that can be interconverted by rotating about single bonds: they are all different conformations of the same molecule.

three compounds, each shown in two conformations

The next block of molecules is something quite different: these pairs can only be interconverted by breaking a bond. This means that they have different configurations—configurations can be interconverted only by breaking bonds. Compounds with different configurations are called stereoisomers and we dealt with them in Chapter 14.

three pairs of stereoisomers: each member of a pair has a different configuration

**Rotation or bond breaking?**

- Structures that can be interconverted simply by rotation about single bonds are conformations of the same molecule.
- Structures that can be interconverted only by breaking one or more bonds have different configurations, and are stereoisomers.
**Conformation and configuration**

**Barriers to rotation**

We saw in Chapter 7 that rotation about the C–N bond in an amide is relatively slow at room temperature—the NMR spectrum of DMF clearly shows two methyl signals (p. 156). In Chapter 12 you learned that the rate of a chemical process is associated with an energy barrier (this holds both for reactions and simple bond rotations): the lower the rate, the higher the barrier. Rotation about single bonds is fast at room temperature, but there is nonetheless a barrier to rotation in ethane (A), for example, of about 12 kJ mol$^{-1}$.

![energy barriers](image)

The energy barrier for rotation about the single bond in butadiene (B) is slightly larger because of the weak conjugation between the double bonds, but the barrier to rotation about the genuine double bond in but-2-ene (D) is enormous and no rotation is seen. The energy barrier to the rotation about the C–N bond in an amide such as DMF (C) is usually about 80 kJ mol$^{-1}$, translating into a rate of about 0.1 s$^{-1}$ at 20 °C. The conjugation in amides is well developed, and the C–N bond has significant double-bond character.
Rates and barriers

It can be useful to remember some simple guidelines to the way in which energy barriers relate to rates of rotation, as discussed in Chapter 12. For example:

- A barrier of 73 kJ mol$^{-1}$ allows one rotation every second at 25 °C (that is, the rate is 1 s$^{-1}$).
- Every 6 kJ mol$^{-1}$ changes the rate at 25 °C by about a factor of 10.

To see signals in an NMR spectrum for two different conformations, they must interconvert no faster than (very roughly) 1000 s$^{-1}$—a barrier of about 55 kJ mol$^{-1}$ at 25 °C. This is why NMR shows two methyl signals for DMF, but only one set of signals for butadiene. See p. 374 for more on this.

For conformations to interconvert slowly enough for them to exist as different compounds, the barrier must be over 100 kJ mol$^{-1}$. The barrier to rotation about a C=C double bond is 260 kJ mol$^{-1}$—which is why we can separate E and Z isomers.

Conformations of ethane

Why should there be an energy barrier in the rotation about a single bond? In order to answer this question, we should start with the simplest C–C bond possible—the one in ethane. Ethane has two extreme conformations called the staggered and eclipsed conformations. Three different views of these are shown below.

You can see why the conformations have these names by looking at the end-on views in the diagram. In the eclipsed case the near C–H bonds completely block the view of the far bonds, just as in a solar eclipse the Moon blocks the Sun as seen from the Earth. In the staggered conformation, the far C–H bonds appear in the gaps between the near C–H bonds—the bonds are staggered.

Chemists often want to draw these two conformations quickly and two different methods are commonly used, each with its own merits. In the first method, shown on the right, we simply draw the side view of the molecule and use wedged and hashed lines to show bonds not in the plane of the paper (as you saw in Chapter 14). Particular attention must be paid to which of the bonds are in the plane and which go into and out of the plane.

In the second method we draw the end-on view, looking along the C–C bond. This view is known as a Newman projection, and Newman projections are subject to a few conventions:

- The carbon atom nearer the viewer is at the junction of the front three bonds.
- The carbon further away (which can’t in fact be seen in the end-on view) is represented by a large circle. This makes the perspective inaccurate, but this doesn’t matter.
- Bonds attached to this further carbon join the edge of the circle and do not meet in the centre.
- Eclipsed bonds are drawn slightly displaced for clarity—as though the bond were rotated by a tiny fraction.

Newman projections of the staggered and eclipsed conformations of ethane

The staggered and eclipsed conformations of ethane are not identical in energy: the staggered conformation is lower in energy than the eclipsed by 12 kJ mol\(^{-1}\), the value of the rotational barrier. Of course, there are other possible conformations too with energies in between these extremes, and we can plot a graph to show the change in energy of the system as the C–C bond rotates. We define the dihedral angle, \(\theta\) (sometimes called the torsion angle), to be the angle between a C–H bond at the nearer carbon and a C–H bond at the far carbon. In the staggered conformation, \(\theta = 60^\circ\) whilst in the eclipsed conformation, \(\theta = 0^\circ\).

The energy level diagram shows the staggered conformation as a potential energy minimum whilst the eclipsed conformation represents an energy maximum. This means that the eclipsed conformation is not a stable conformation since any slight rotation will lead to a conformation lower in energy. The molecule will actually spend the vast majority of its time in a staggered or nearly staggered conformation and only briefly pass through the eclipsed conformation en route to another staggered conformation.

But why is the eclipsed conformation higher in energy than the staggered conformation? There are two reasons. The first is that the electrons in the bonds repel each other and this repulsion is at a maximum when the bonds are aligned in the eclipsed conformation. The second is that there may be some stabilizing interaction between the C–H \(\sigma\) bonding orbital on one carbon and the C–H \(\sigma^*\) antibonding orbital on the other carbon, which is greatest when the two orbitals are exactly parallel: this only happens in the staggered conformation. The same effects—repulsion between filled orbitals (a form of steric effect, see p. 129) and stabilization by donation into antibonding orbitals—govern the favoured conformations about all rotating bonds.
Conformations of propane

Propane is the next simplest hydrocarbon. Before we consider what conformations are possible for propane we should first look at its geometry. The C–C–C bond angle is not 109.5° (the tetrahedral angle, see Chapters 2 and 4) as we might expect, but 112.4°. Consequently, the H–C–H bond angle on the central carbon is smaller than the ideal angle of 109.5°, only 106.1°. This does not necessarily mean that the two methyl groups on the central carbon clash in some way, but instead that two C–C bonds repel each other more than two C–H bonds do.

As in the case of ethane, two extreme conformations of propane are possible—in one the C–H and C–C bonds are staggered, in the other they are eclipsed.

The rotational barrier is now slightly higher than for ethane: 14 kJ mol\(^{-1}\) as compared to 12 kJ mol\(^{-1}\). This again reflects the greater repulsion of electrons in the coplanar bonds in the eclipsed conformation rather than any steric interactions. The energy graph for bond rotation in propane would look exactly the same as that for ethane except that the barrier is now 14 kJ mol\(^{-1}\).

Conformations of butane

With butane things start to get slightly more complicated. Now we have effectively replaced two hydrogen atoms in ethane by larger methyl groups. These are large enough to get in the way of each other, and steric repulsion becomes a significant contribution to the rotational energy barriers. However, the main complication is that, as we rotate about the central C–C bond, not all the staggered conformations are the same, and neither are all the eclipsed conformations. The six conformations that butane can adopt as the central C–C bond is rotated in 60° intervals are shown below. The green Me group and the brown hydrogens are rotating while the substituents on the other carbon atom remain still.

Look closely at these different conformations. The conformations with dihedral angles 60° and 300° are actually mirror images of each other, as are the conformations with angles 120° and 240°. This means that we really only have four different maxima or minima in energy as we rotate about the central C–C bond: two types of eclipsed conformation, which will represent maxima in the energy–rotation graph, and two types of staggered conformation, which will represent minima. These four different conformations have names, shown in the bottom row of the diagram. In the syn-periplanar and anti-periplanar conformations the two C–Me bonds lie in the same plane; in the synclinal (or gauche) and anticlinal conformations they slope towards (syn) or away from (anti) one another.
Before we draw the energy–rotation graph, let’s just stop and think what it might look like. Each of the eclipsed conformations will be energy maxima but the syn-periplanar conformation \( (\theta = 0^\circ) \) will be higher in energy than the two anticlinal conformations \( (\theta = 120^\circ \text{ and } 240^\circ) \): in the syn-periplanar conformation two methyl groups are eclipsing each other whereas in the anticlinal conformations each methyl group is eclipsing only a hydrogen atom. The staggered conformations will be energy minima but the two methyl groups are furthest from each other in the anti-periplanar conformation so this will be a slightly lower minimum than the two synclinal (gauche) conformations.

As in ethane, the eclipsed conformations are not stable since any rotation leads to a more stable conformation. The staggered conformations are stable since they each lie in a potential energy well. The anti-periplanar conformation, with the two methyl groups opposite each other, is the most stable of all. We can therefore think of a butane molecule as rapidly interconverting between synclinal and anti-periplanar conformations, passing quickly through the eclipsed conformations on the way. The eclipsed conformations are energy maxima, and therefore represent the transition states for interconversion between conformations.

If we managed to slow down the rapid interconversions in butane (by cooling to very low temperature, for example), we would be able to isolate the three stable conformations—the anti-periplanar and the two synclinal conformations. These different stable conformations of butane are some sort of isomers. They are called conformational isomers or conformers for short.

You now have a more thorough explanation of the zig-zag arrangement of carbon chains, first introduced in Chapter 2 when we showed you how to draw molecules realistically. This is the shape you get if you allow all the C–C bonds to take up the anti-periplanar conformation, and it will be the most stable conformation for any linear alkane.

**Ring strain**

Up to now, we haven’t given an entirely accurate impression of rings. We have been drawing them all as though they were planar, although this is actually not the case. In this section you will learn how to draw rings more accurately and to understand the properties of the different conformations adopted.

If we assume that in fully saturated carbocyclic rings each carbon is sp\(^3\) hybridized, then each bond angle would ideally be 109.5°. However, in a planar ring, the carbon atoms don’t
have the luxury of choosing their bond angles: internal angle depends only on the number of
atoms in the ring. If this angle differs from the ideal 109.5°, there will be some sort of strain
in the molecule. This is best seen in the picture below, where the atoms are forced planar. The
more strained the molecules are, the more the bonds curve—in a strain-free molecule, the
bonds are straight.

Notice how in the smaller rings the bonds curve outwards, whilst in the larger rings the
bonds curve inwards. The table gives values for the internal angles for regular planar polygons
and an indication of the strain per carbon atom due to the deviation of this angle from the
ideal tetrahedral angle of 109.5°.

These data are best presented as a graph, and the ring strain per carbon atom in planar rings
for ring sizes up to 17 are shown on the next page. Whether the bonds are strained inwards or
outwards is not important so only the magnitude of the strain is shown.

From these figures (represented in the graph on p. 368), note:

- These are calculated data for hypothetical planar rings. As you will see, real rings are
  rather different.
- The calculated ring strain is largest for three-membered rings but rapidly decreases
  through a four-membered ring and reaches a minimum for a five-membered ring.
- The calculated ring strain increases again (although less rapidly) as the rings get larger
  after the minimum at 5.

But what we really need is a measure of the strain in actual compounds, not just a theoreti-
cal prediction in planar rings, so that we can compare this with the theoretical angle strain.
A good measure of the strain in real rings is obtained using heats of combustion. Look at the
following heats of combustion for some straight-chain alkanes. What is striking is that the
difference between any two in the series is very nearly constant at around –660 kJ mol⁻¹.

If we assume (as is reasonable) that there is no strain in the straight-chain alkanes, then each
extra methylene group, –CH₂–, contributes on average an extra 658.7 kJ mol⁻¹ to the heat of
combustion for the alkane. A cycloalkane (CH₂)n is simply a number of methylene groups
joined together. If the cycloalkane is strain-free, then its heat of combustion should be n × 658.7
kJ mol⁻¹. If, however, there is some strain in the ring that makes the ring less stable (that is,
raises its energy) then more energy is given out on combustion. Now, let’s put all this together
in a graph showing, for each ring size: (a) angle strain per CH₂ group and (b) heat of combus-
tion per CH₂ group.
Points to notice in graph above:

- The greatest strain by far is in the three-membered ring, cyclopropane \( n = 3 \).
- The strain decreases rapidly with ring size but reaches a minimum for cyclohexane, not cyclopentane as you might have predicted from the angle calculations.
- The strain then increases but not nearly as quickly as the angle calculation suggested: it reaches a maximum at around \( n = 9 \) and then decreases once more.
- The strain does not go on increasing as ring size increases but instead remains roughly constant after about \( n = 14 \).
- Cyclohexane \( n = 6 \) and the larger cycloalkanes \( n \geq 14 \) all have heats of combustion per \(-\text{CH}_2\) group of around 658 kJ mol\(^{-1}\), the same value as that of a \(-\text{CH}_2\) group in a straight-chain alkane, that is, they are essentially strain-free.

You might ask yourself some questions now:

Why are six-membered rings and large rings virtually strain-free?

Why is there still some strain in five-membered rings even though the bond angles in a planar structure are almost 109.5°?

The answer to both these questions, as you may already have guessed, is that the assumption that the rings are planar is simply not correct. It is easy to see how large rings can fold up into many different conformations as easily as acyclic compounds do. It is less clear to predict what happens in six-membered rings.

**Six-membered rings**

If you were to join six tetrahedral carbon atoms together, you would probably find that you ended up with a shape like this.

All the carbon atoms are certainly not in the same plane, and there is no strain because all the bond angles are 109.5°. If you squash the model against the desk, forcing the atoms to lie in the same plane, it springs back into this shape as soon as you let go. If you view the model from one side (the second picture above) you will notice that four carbon atoms lie in the same plane, with the fifth above the plane and the sixth below it (although it’s important to realize that all six are identical—you can check this by rotating your model). The slightly overly imaginative name for this conformation—the **chair conformation**—derives from this view.
There is another conformation of cyclohexane that you might have made that looks like this.

This conformation is known as the **boat conformation**. In this conformation there are still four carbon atoms in one plane, but the other two are both above this plane. Now all the carbon atoms are not the same—the four in the plane are different from the ones above. However, this is not a stable conformation of cyclohexane, even though there is no bond angle strain (all the angles are 109.5°). In order to understand why not, we must go back a few steps and answer our other question: why is cyclopentane strained even though a planar conformation has virtually no angle strain?

**Smaller rings (three, four, and five members)**

The three carbon atoms in cyclopropane must lie in a plane since it is always possible to draw a plane through any three points. All the C–C bond lengths are the same, which means that the three carbon atoms are at the corners of an equilateral triangle. From the large heat of combustion per methylene group (p. 368) we know that there is considerable strain in this molecule. Most of this is due to the bond angles deviating so greatly from the ideal tetrahedral value of 109.5°. Most—but not all. If we view along one of the C–C bonds we can see a further cause of strain—all the C–H bonds are eclipsed.

The eclipsed conformation of ethane is an energy maximum and any rotation leads to a more stable conformation. In cyclopropane it is not possible to rotate any of the C–C bonds and so all the C–H bonds are forced to eclipse their neighbours. In fact, in any planar conformation all the C–H bonds will be eclipsed with their neighbours. In cyclobutane, the ring distorts from a planar conformation in order to reduce the eclipsing interactions, even though this reduces the bond angles further and so increases the bond angle strain. Cyclobutane adopts a puckered or ‘wing-shaped’ conformation.
This explains why cyclopentane is not entirely strain-free even though in a planar conformation the C–C–C bond angles are close to 109.5°. The heat of combustion data give us an indication of the total strain in the molecule, not just the contribution of angle strain. There is strain in planar cyclopentane caused by the eclipsing of adjacent C–H bonds. As in cyclobutane, the ring distorts to reduce the eclipsing interactions but this increases the angle strain. Whatever happens, there is always going to be some strain in the system. The minimum energy conformation adopted is a balance of the two opposing effects. Cyclopentane adopts a shape approximating to an ‘open envelope’, with four C atoms in a plane and one above or below it. The atoms in the ring rapidly take turns not to be in the plane, and cyclopentanes have much less well-defined conformational properties than cyclohexanes, to which we shall now return.

A closer look at cyclohexane

The heats of combustion data on p. 368 show that cyclohexane is virtually strain-free. This must mean that not only is there no angle strain, but there is also no strain from eclipsing interactions either. A model of the chair conformation of cyclohexane including all the hydrogen atoms looks like this.

The view along two of the C–C bonds clearly shows that there are no eclipsing C–H bonds in the chair conformation of cyclohexane—in fact, all the bonds are fully staggered, giving the lowest energy possible. This is why cyclohexane is strain-free. Contrast this with the boat conformation. Now four pairs of C–H bonds are eclipsed, and there is a particularly bad interaction between the ‘flagstaff’ C–H bonds.

This explains why the boat conformation is much less important than the chair conformation. Even though both are free from angle strain, the eclipsing interactions in the boat conformation make it approximately 25 kJ mol⁻¹ higher in energy than the chair conformation. In fact, as we shall see later, the boat conformation represents an energy maximum in cyclohexane whilst the chair conformation is an energy minimum. Earlier we saw how the eclipsing interactions in planar cyclobutane and cyclopentane could be reduced by distortion of the ring. The same is true for the boat conformation of cyclohexane. The eclipsing interactions can be relieved slightly if the two ‘side’ C–C bonds twist relative to each other.
Pushing these two carbon atoms in the direction shown... gives a slightly different conformation in which the eclipsing interactions have been reduced: the 'twist-boat' conformation shows the reduced eclipsing interactions.

This twisting gives rise to a slightly different conformation of cyclohexane called the twist-boat conformation, which, although not as low in energy as the chair form, is lower in energy (by 4 kJ mol\(^{-1}\)) than the boat form and is a local energy minimum, as we shall see later. Cyclohexane has two stable conformers, the chair and the twist-boat. The chair form is approximately 21 kJ mol\(^{-1}\) lower in energy than the twist-boat form.

**Axial and equatorial**

Take another look at the chair conformation on p. 368. All six carbon atoms are identical, but there are two types of protons—one type stick either vertically up or down and are called axial hydrogen atoms; the other sort stick out sideways and are called equatorial hydrogen atoms. As you go round the ring, notice that each of the CH\(_2\) groups has one hydrogen sticking up and one sticking down. However, all the ‘up’ ones alternate between axial and equatorial, as do all the ‘down’ ones.

Before going any further, it’s important that you learn how to draw cyclohexane properly. Without cluttering the structure with Cs and Hs, a chemist would draw cyclohexane as one of these three structures.

Up to now, we have simply used the hexagon A to represent cyclohexane. We shall see that, whilst this is the least informative of the three, it is nonetheless still useful. The more informative structures B and C (which are actually just different views of the same molecule) take some practice to draw properly, but you need to be able to draw convincing cyclohexanes and it is worth taking the time to learn how to now.

**Guidelines for drawing cyclohexane**

**The carbon skeleton**

Trying to draw the chair conformation of cyclohexane in one continuous line can lead to some dreadful diagrams. The easiest way to draw a chair conformation is by starting off with one end.

Next draw in two parallel lines of equal length.

At this stage, the top of the new line should be level with the top of the original pair.

Finally, the last two lines should be added. These lines should be parallel to the first pair of lines as shown and the lowest points should also be level.
Adding the hydrogen atoms

This is often the trickiest part. Just remember that you are trying to make each of the carbon atoms look tetrahedral. (Note that we don’t normally use wedged and hashed bonds in these chair-shaped diagrams; otherwise things get really messy.)

The axial bonds are relatively easy to draw in. They should all be vertically aligned and alternate up and down all round the ring.

The equatorial bonds require a little more care to draw. The thing to remember is that each equatorial bond must be parallel to two C–C bonds.

The complete diagram with all the hydrogen atoms should look like this. Most of the time you won’t want to draw in all the Hs but you need to know how to orientate them in case you do need to.

Common mistakes

If you follow all the guidelines above, you will soon be drawing good conformational diagrams. However, a few common mistakes have been included to show you what not to do!

how not to draw cyclohexanes...

The chair has been drawn with the middle bonds horizontal, so the upper points of the chair are not level. This means the axial hydrogens can no longer be drawn correctly vertical.

The axial hydrogens have been drawn alternating up and down on the wrong carbons. This structure is impossible because none of the carbons can be tetrahedral.

The red hydrogens have been drawn at the wrong angles—look for the parallel lines and the ‘W’ and ‘M’.
The ring inversion (flipping) of cyclohexane

Given that this chair conformer is the preferred conformation for cyclohexane, what would you expect its $^{13}$C NMR spectrum to look like? All six carbon atoms are the same so there should only be one signal (and indeed there is, at 25.2 ppm). But what about the $^1$H NMR spectrum? The two different sorts of protons (axial and equatorial) ought to resonate at different frequencies, so two signals should be seen (each with coupling to neighbouring protons). In fact, there is only one resonance in the proton spectrum, at 1.40 ppm. In a monosubstituted cyclohexane there should be two isomers detectable—one with the substituent axial, the other with the substituent equatorial. But again at room temperature only one set of signals is seen.

This changes when the NMR spectrum is run at low temperature. Now two isomers are visible, and this gives us a clue as to what is happening: the two isomers are conformers that interconvert—rapidly at room temperature, but more slowly when the temperature is lowered. Recall that NMR does not distinguish between the three different stable conformers of butane (two synclinal and one anti-periplanar) because they are all rapidly interconverting so fast that only an average is seen. The same happens with cyclohexane—just by rotating bonds (that is, without breaking any!) cyclohexane can ring invert or ‘flip’. After ring inversion has taken place, all the bonds that were axial are now equatorial and vice versa.

The whole inversion process can be broken down into the conformations shown below. The green arrows show the direction in which the individual carbon atoms should move in order to get to the next conformation.

The energy profile (below) for this ring inversion shows that the half-chair conformation is the energy maximum on going from a chair to a twist-boat. The true boat conformation is the energy maximum on interchanging between two mirror-image twist-boat conformers, the second of which is converted to the other chair conformation through another half-chair.

This would be a good point to remind you again of Chapter 12. This energy profile shows the conversion of one chair to another via two twist-boat intermediates (local energy minima). In between the energy minima are energy maxima, which are the transition states for the process. The progress of the ring-flipping ‘reaction’ is shown along an arbitrary ‘reaction coordinate’.

Interactive conformations of cyclohexane
Drawing other cyclohexane conformations

In the half-chair conformation of cyclohexane, four adjacent carbon atoms are in one plane with the fifth above this plane and the sixth below it. You will meet this conformation again later—it represents the energy minimum for cyclohexene, for example.

There are also a number of ways of drawing a twist-boat conformer but the easiest is this:

It’s clear from the diagram that the barrier to ring inversion of cyclohexane is 43 kJ mol⁻¹, a rate at 25°C of about 2 × 10⁵ s⁻¹. Ring inversion also interconverts the axial and equatorial protons, so these are also exchanging at a rate of 2 × 10⁵ s⁻¹ at 25°C—too fast for them to be detected individually by NMR, which is why they appear as an averaged signal.

Rates and spectroscopy

NMR spectrometers behave like cameras with a shutter speed of about 1/1000 s. Anything happening faster than that, and we get a blurred picture; things happening more slowly give a sharp picture. In fact, a more exact number for the ‘shutter speed’ of an NMR machine (not a real shutter speed—just figuratively speaking!) is given by the equation

\[ k = \pi \Delta \nu / \sqrt{2} = 2.22 \times \Delta \nu \]

where \( k \) is the fastest exchange rate that still gives individual signals and \( \Delta \nu \) is the separation of those signals in the NMR spectrum measured in hertz. For example, on a 400 MHz spectrometer, two signals separated by 0.5 ppm are 100 Hz apart, so any process exchanging with a rate slower than 222 s⁻¹ will still allow the NMR machine to show two separate signals; if they exchange with a rate faster than 222 s⁻¹ only an averaged signal will be seen.

The equation above holds for any spectroscopic method, provided we think in terms of differences between signals or peaks measured in hertz. So, for example, a difference between two IR absorptions of 100 cm⁻¹ can be represented as a wavelength of 0.01 cm (1 × 10⁻⁴ m) or a frequency of 3 × 10¹² s⁻¹. IR can detect changes happening a lot faster than NMR can—its ‘shutter speed’ is of the order of one-trillionth of a second.

Substituted cyclohexanes

In a monosubstituted cyclohexane, there can exist two different chair conformers: one with the substituent axial, the other with it equatorial. The two chair conformers will be in rapid equilibrium (by the process we have just described) but they will not have the same energy. In almost all cases, the conformer with the substituent axial is higher in energy, which means there will be less of this form present at equilibrium.

For example, in methylcyclohexane (X = CH₃), the conformer with the methyl group axial is 7.3 kJ mol⁻¹ higher in energy than the conformer with the methyl group equatorial. This energy difference corresponds to a 20:1 ratio of equatorial:axial conformers at 25°C.

There are two reasons why the axial conformer is higher in energy than the equatorial conformer. The first is that the axial conformer is destabilized by the repulsion between the axial group X and the two axial hydrogen atoms on the same side of the ring. This interaction is known as the 1,3-diaxial interaction. As the group X gets larger, this interaction becomes more severe and there is less of the conformer with the group axial. The second reason is that
in the equatorial conformer the C–X bond is anti-periplanar to two C–C bonds, while, for the axial conformer, the C–X bond is synclinal (gauche) to two C–C bonds.

The table shows the preference of a number of substituted cyclohexanes for the equatorially substituted conformer over the axially substituted conformer at 25 °C.

Note the following points (also referred to in Chapter 12).

- The three columns in the table are three different ways of expressing the same information. However, just looking at the percentages column, it is not immediately obvious to see how much more of the equatorial conformer there is—after all, the percentages of equatorial conformer for methyl, ethyl, isopropyl, t-buty1, and phenyl-cyclohexanes are all 95% or more. Looking at the equilibrium constants gives a much clearer picture.

- The amount of equatorial conformer present does increase in the order Me < Et < i-Pr < t-Bu, but perhaps not quite as expected. The ethyl group must be physically larger than a methyl group but there is hardly any difference in the equilibrium constants. The increase in the proportion of equatorial conformer on going from Et to i-Pr is only a factor of two, but for t-buty1cyclohexane it is estimated that there is about 3000 times more of the equatorial conformer than the axial conformer.

- The same anomaly occurs with the methoxy group—there is a much greater proportion of the conformer with a methoxy group axial than with a methyl group axial. This is despite the fact that a methoxy group is physically larger than a methyl group.

- The equilibrium constant does not depend on the actual size of the substituent, but rather its interaction with the neighbouring axial hydrogens. In the axial conformer of methylcyclohexane there is a direct interaction between the methyl group and the axial hydrogen atoms.

- In the case of the methoxy group, the oxygen acts as link and removes the methyl group away from the ring, lessening the interaction.
• The groups Me, Et, i-Pr, and t-Bu all need to point some atom towards the other axial hydrogens, and for Me, Et, and i-Pr this can be H.

• Only for t-Bu must a methyl group be pointing straight at the axial hydrogens, so t-Bu has a much larger preference for the equatorial position than the other alkyl groups. In fact, the interactions between an axial t-Bu group and the axial hydrogen atoms are so severe that the group virtually always stays in the equatorial position. As we shall see later, this can be very useful.

What happens with more than one substituent on the ring?

When there are two or more substituents on the ring, stereoisomerism is possible. For example, there are two isomers of 1,4-cyclohexanediol—in one (the cis isomer) both the substituents are either above or below the cyclohexane ring; in the other (the trans isomer) one hydroxyl group is above the ring whilst the second is below. For a cis 1,4-disubstituted cyclohexane with both the substituents the same, ring inversion leads to a second identical conformation, while for the trans configuration there is one conformation with both groups axial and one with both groups equatorial.

The chair-structure diagrams contain much more information than the simple ‘hexagon’ diagrams that we have used up to now. The former show both configuration and conformation—they show which stereoisomer (cis or trans) we are talking about and also (for the trans compound) the conformation adopted (diaxial or the more stable diequatorial). In contrast, the simpler hexagon diagrams carry no information about the conformation—only information about which isomer we are dealing with. This can be useful because it enables us to talk about one configuration of a compound without specifying the conformation. When you are solving a problem requiring conformational diagrams to predict the configuration of a product, always start and finish with a configurational (hexagon) drawing.

The chair conformer of cis-1,4-disubstituted cyclohexane has one substituent equatorial, the other axial. This will not necessarily be the case for other substitution patterns, for example the chair conformer of a cis-1,3-disubstituted cyclohexane has either both substituents axial or both equatorial. Remember, the ‘cis’ and ‘trans’ prefixes merely indicate that both groups are on the same ‘side’ of the cyclohexane ring. Whether the substituents are both axial/equatorial or one axial and the other equatorial depends on the substitution pattern. Each time you meet a molecule, draw the conformation or make a model to find out which bonds are axial and which are equatorial.
What if the two substituents on the ring are different? For the cis-1,3-disubstituted example above, there is no problem because the favoured conformation will still be the one that places these two different substituents equatorial. But when one substituent is axial and the other equatorial (as they happen to be in the trans diastereoisomer above) the preferred conformation will depend on what those substituents are. In general, the favoured conformation will place the maximum number of substituents equatorial. If both conformations have the same number of equatorial substituents, the one with the larger substituent equatorial will win out, and the smaller group will be forced to be axial. Various possibilities are included in the examples below.

This is only a guideline, and in many cases it is not easy to be sure. Instead of concerning ourselves with these uncertainties, we shall move on to some differentially substituted cyclohexanes for which it is absolutely certain which conformer is preferred.

**Locking groups—t-butyI groups, decalins, and steroids**

We have already seen how a t-butyI group always prefers an equatorial position in a ring. This makes it very easy to decide which conformation the two different compounds below will adopt.
cis-1,4-di-t-butylcyclohexanol

An axial t-butyl group really is very uncomfortable. In cis-1,4-di-t-butylcyclohexane, one t-butyl group would be forced axial if the compound existed in a chair conformation. To avoid this, the compound prefers to pucker into a twist-boat so that the two large groups can both be in equatorial positions (or ‘pseudoequatorial’, since this is not a chair).

Decalins

It is also possible to lock the conformation of a cyclohexane ring by joining another ring to it. Decalin is two cyclohexane rings fused at a common C–C bond. Two diastereoisomers are possible, depending on whether the hydrogen atoms at the ring junction are cis or trans. For cis-decalin, the second ring has to join the first so that it is axial at one point of attachment and equatorial at the other; for trans-decalin, the second ring can be joined to the first in the equatorial position at both attachment points.

When a cyclohexane ring inverts, the substituents that were equatorial become axial and vice versa. This is fine for cis-decalin, which has an axial–equatorial junction, but it means that ring inversion is not possible for trans-decalin. For trans-decalin to invert, the junction would have to become axial–axial, and it’s not possible to link the axial positions to form a six-membered ring. Cis-decalin, on the other hand, ring inverts easily.

Flipping cis-decalin: not so difficult once you know how

If you find it hard to visualize the ring inversion of cis-decalin, you are not alone! The best way to think about it is to ignore the second ring until the very end: just concentrate on what happens to one ring (black in this diagram), the hydrogens at the ring junction, and the (orange) bonds next to these hydrogens that form the ‘stumps’ of the second ring. Flip the black ring, and the ‘stumps’, and the hydrogens swap from axial to equatorial and vice versa. Draw the result, but don’t fill in the second ring yet or it will usually just come out looking like a flat hexagon (as in diagram A). Instead, rotate the complete (black) ring 60° about a vertical axis so that both of the orange ‘stumps’ can form part of a chair, which can now be filled in (diagram B). To make a chair (and not a hexagon) they must be pointing in a convergent direction, as the orange bonds are in B but not A.
Steroids

Steroids are an important class of compounds occurring in all animals and plants, which have many important functions from regulating growth (anabolic steroids) and sex drive (all sex hormones are steroids) to acting as a self-defence mechanism in plants, frogs, and even sea cucumbers. A steroid is defined by its structure: all steroids contain a basic carbon framework consisting of four fused rings—three cyclohexane rings and one cyclopentane ring—labelled and joined together as shown in the margin.

Just as in the decalin system, each ring junction could be cis or trans, but it turns out that all steroids have all trans-junctions except where rings A and B join, which is sometimes cis. Examples are cholestanol (all trans) and coprostanol (A and B fused cis).

Because steroids (even those with a cis A–B ring junction) are essentially substituted trans-decalins, they can’t ring-flip. This means, for example, that the hydroxyl group in cholestanol is held equatorial on ring A while the hydroxyl group in coprostanol is held axial on ring A. The steroid skeleton really is remarkably stable—samples of sediment 1.5 × 10⁹ years old have been found to contain steroids still with the same ring-junction stereochemistry.

**Axially and equatorially substituted rings react differently**

We shall be using ring structures throughout the rest of the book, and you will learn how their conformation affects their chemistry extensively. In many reactions of six-membered rings, the outcome may depend on whether a functional group is axial or equatorial. We shall conclude this chapter with two examples in which a functional group will be held in its axial or equatorial position by ‘locking’ the ring using a t-butyl group or a fused ring system such as trans-decalin.

In the last chapter we looked at two mechanisms for nucleophilic substitution: S_N1 and S_N2. We saw that the S_N2 reaction involved an inversion at the carbon centre. Recall that the incoming nucleophile had to attack the σ* orbital of the C–X bond. This meant that it had to approach the leaving group directly from behind, leading to inversion of configuration.
inversion during nucleophilic substitution at saturated carbon

What do you think would happen if a cyclohexane derivative underwent an $S_n2$ reaction? If the conformation of the molecule is fixed by a locking group, the inversion mechanism of the $S_n2$ reaction means that, if the leaving group is axial, then the incoming nucleophile will end up equatorial and vice versa.

Substitution reactions are not very common for substituted cyclohexanes. The electrophilic carbon in a cyclohexane ring is a secondary centre—in the last chapter we saw that secondary centres do not react well via either $S_n1$ or $S_n2$ mechanisms (p. 347). To encourage an $S_n2$ mechanism, we need a good attacking nucleophile and a good leaving group. One such example is shown—the substitution of tosylate by $\text{PhS}^-$. The substitution of an axial substituent proceeds faster than the substitution of an equatorial substituent. There are several contributing factors making up this rate difference, but the most important is the direction of approach of the nucleophile. The nucleophile must attack the $\sigma^*$ of the leaving group, that is, directly behind the $\text{C–X}$ bond. In the case of an equatorially substituted compound, this line of attack is hindered by the (green) axial hydrogens—it passes directly through the region of space they occupy. For an axial leaving group, the direction of attack is parallel with the (orange) axial hydrogens anti-periplanar to the leaving group, and approach is much less hindered.
We must assume that this holds even for simple unsubstituted cyclohexanes, and that substitution reactions of cyclohexyl bromide, for example, occur mainly on the minor, axial conformer. This slows down the reaction because before it can react, the prevalent equatorial conformer must first flip to the axial.

If this flip to an axial leaving group is not possible, it may be that the reaction just won’t happen at all. This is exactly what happens in a trans-decalin. There are two diastereoisomers of this simple substituted trans-decalin: one with an equatorial and one with an axial leaving group (X could be Br, OTs, etc.).

![Equatorial vs. Axial Leaving Groups](image)

Attack by a nucleophile on the compound with the axial leaving group is straightforward. The nucleophile can approach along the axis of the C–X bond and normal SN₂ reaction occurs with inversion—the product is the equatorial compound. The equatorial leaving group, on the other hand, would require the nucleophile to approach through the middle of the molecule and that cannot be achieved. A totally different reaction occurs—a rearrangement that you will meet in Chapter 36.

**To conclude...**

You may wonder why we have spent most of this chapter looking at six-membered rings, ignoring other ring sizes almost totally. Apart from the fact that six is the most widespread ring size in organic chemistry, the reactions of six-membered rings are also the easiest to explain and to understand. The conformational principles we have outlined for six-membered rings (relief of ring strain, staggered favoured over eclipsed, equatorial favoured over axial, direction of attack) hold, in modified form, for other ring sizes as well. These other rings are less well behaved than six-membered rings because they lack the well-defined strain-free conformations that cyclohexane is blessed with. We shall now leave stereochemistry in rings for some time, but we come back to these more difficult rings—and how to tame them—in two chapters on stereochemistry in cyclic compounds, Chapters 31 and 32.

**Further reading**

**Check your understanding**

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)

Substitution and elimination

Substitution reactions of t-butyl halides, you will recall from Chapter 15, invariably follow the S_N1 mechanism. In other words, the rate-determining step of their substitution reactions is unimolecular—it involves only the alkyl halide. This means that, no matter what the nucleophile is, the reaction goes at the same rate. You can’t speed this S_N1 reaction up, for example, by using hydroxide instead of water, or even by increasing the concentration of hydroxide. You’d be wasting your time, we said (see p. 332).

Nucleophilic substitution reactions of t-BuBr

You’d also be wasting your alkyl halide. This is what actually happens if you try the substitution reaction with a concentrated solution of sodium hydroxide.

Reaction of t-BuBr with concentrated solution of NaOH

Remember the turnstiles at the railway station (see p. 332).

The reaction stops being a substitution and an alkene is formed instead. Overall, HBr has been lost from the alkyl halide, and the reaction is called an elimination.

In this chapter we will talk about the mechanisms of elimination reactions—as in the case of substitutions, there is more than one mechanism for eliminations. We will compare eliminations with substitutions—either reaction can happen from almost identical starting materials, and you will learn how to predict which is the more likely. Much of the mechanistic discussion relates very closely to Chapter 15, and we suggest that you make sure you understand all of the points in that chapter before tackling this one. This chapter will also tell you about uses for elimination reactions. Apart from a brief look at the Wittig reaction in Chapter 11, this is the first time you have met a way of making simple alkenes.

**Elimination happens when the nucleophile attacks hydrogen instead of carbon**

The elimination reaction of t-buty1 bromide happens because the nucleophile is basic. You will recall from Chapter 10 that there is some correlation between basicity and nucleophilicity: strong bases are usually good nucleophiles. Being a good nucleophile doesn’t get hydroxide anywhere in the substitution reaction because it doesn’t appear in the first-order rate equation. But being a good base does get it somewhere in the elimination reaction because hydroxide is involved in the rate-determining step of the elimination, and so it appears in the rate equation. This is the mechanism.

\[
\text{rate} = k_2 \left[ \text{t-BuBr} \right] \left[ \text{HO}^- \right]
\]

The hydroxide is behaving as a base because it is attacking the hydrogen atom, instead of the carbon atom it would attack in a substitution reaction. The hydrogen atom is not acidic, but proton removal can occur because bromide is a good leaving group. As the hydroxide attacks, the bromide is forced to leave, taking with it the negative charge. Two molecules—t-buty1 bromide and hydroxide—are involved in the rate-determining step of the reaction. This means that the concentrations of both appear in the rate equation, which is therefore second-order and this mechanism for elimination is termed E2, for elimination, bimolecular.

**Note:** No subscripts or superscripts, just plain old E2.

Now let’s look at another sort of elimination. We can approach it again by thinking about another SN1 substitution reaction, the reverse of the one at the beginning of the chapter: an alcohol is converted into an alkyl halide.

Bromide, the nucleophile, is not involved in the rate-determining step, so we know that the rate of the reaction will be independent of the concentration of Br\(^-\). Indeed the first step, to form the cation, will happen just as fast even if there is no bromide at all. But what happens to the carbocation in such a case? To find out, we need to use an acid whose counterion is such a weak nucleophile that it won’t even attack the positive carbon of the carbocation. Here is an example—t-butanol in sulfuric acid doesn’t undergo substitution, but undergoes elimination instead.
The HSO₄⁻ anion is not involved in the rate-determining formation of the carbocation, and is also a very bad nucleophile, so it does not attack the C atom of the carbocation. Neither is it basic, but you can see from the mechanism that it does behave as a base (that is, it removes a proton). It does this only because it is even more feeble as a nucleophile. The rate equation will not involve the concentration of HSO₄⁻ and the rate-determining step is the same as that in the S₅₁ reaction—unimolecular loss of water from the protonated t-BuOH. This elimination mechanism is therefore called E₁.

We will shortly come back to these two mechanisms for elimination, plus a third, but it is worth noting at this stage that the choice between E₁ and E₂ is not based on the same grounds as the choice between S₅₁ and S₅₂: you have just seen both E₁ and E₂ elimination from a substrate that would only undergo S₅₁. The difference between the two reactions was the strength of the base, so first we need to answer the question: when does a nucleophile start behaving as a base?

**Elimination in carbonyl chemistry**

We have left detailed discussion of the formation of alkenes until this chapter, but we used the term ‘elimination’ in Chapters 10 and 11 to describe the loss of a leaving group from a tetrahedral intermediate. For example, the final steps of acid-catalysed ester hydrolysis involve E₁ elimination of ROH to leave a double bond: C=O rather than C=C.

In Chapter 11 you even saw an E₁ elimination giving an alkene. That alkene was an enamine—here is the reaction.

**How the nucleophile affects elimination versus substitution**

**Basicity**

You have just seen molecules bearing leaving groups being attacked at two distinct electrophilic sites: the carbon to which the leaving group is attached, and the hydrogen atoms on the carbon adjacent to the leaving group. Attack at carbon leads to substitution; attack at hydrogen leads to elimination. Since strong bases attack protons, it is generally true that, the more basic the nucleophile, the more likely that elimination is going to replace substitution as the main reaction of an alkyl halide.

Here is an example of this idea at work: a weak base (EtOH) leads to substitution while a strong base (ethoxide ion) leads to elimination.
Elimination, substitution, and hardness

We can also rationalize selectivity for elimination versus substitution, or attack on H versus attack on C in terms of hard and soft electrophiles (p. 357). In an \( \text{SN}_2 \) substitution, the carbon centre is a soft electrophile—it is essentially uncharged, and with leaving groups such as halide the C–X \( \sigma^* \) is a relatively low-energy LUMO. Substitution is therefore favoured by nucleophiles whose HOMOs are best able to interact with this LUMO—in other words soft nucleophiles. In contrast, the C–H \( \sigma^* \) is higher in energy because the atoms are less electronegative. This, coupled with the hydrogen’s small size, makes the C–H bond a hard electrophilic site, and as a result hard nucleophiles favour elimination.

Size

For a nucleophile, attacking a carbon atom means squeezing past its substituents—and even for unhindered primary alkyl halides there is still one alkyl group attached. This is one of the reasons that \( \text{SN}_2 \) is so slow on hindered alkyl halides—the nucleophile has difficulty getting to the reactive centre. Getting at a more exposed hydrogen atom in an elimination reaction is much easier, and this means that, as soon as we start using basic nucleophiles that are also bulky, elimination becomes preferred over substitution, even for primary alkyl halides. One of the best bases for promoting elimination and avoiding substitution is potassium \( t \)-butoxide. The large alkyl substituent makes it hard for the negatively charged oxygen to attack carbon in a substitution reaction, but it has no problem attacking hydrogen.

Temperature

Temperature has an important role to play in deciding whether a reaction is an elimination or a substitution. In an elimination, two molecules become three (count them). In a substitution, two molecules form two new molecules. The two reactions therefore differ in the change in entropy during the reaction: \( \Delta S \) is greater for elimination than for substitution. In Chapter 12, we discussed the equation

\[
\text{This explanation is simplified because what matters is the rate of the reaction, not the stability of the products. A detailed discussion is beyond the scope of the book, but the general argument still holds.}
\]
This equation says that a reaction in which $\Delta S$ is positive becomes more favourable ($\Delta G$ becomes more negative) at higher temperature. Eliminations should therefore be favoured at high temperature, and this is indeed the case: most eliminations you will see are conducted at room temperature or above.

- Elimination versus substitution
  - Nucleophiles that are strong bases favour elimination over substitution.
  - Nucleophiles (or bases) that are bulky favour elimination over substitution.
  - High temperatures favour elimination over substitution.

**E1 and E2 mechanisms**

Now that you have seen a few examples of elimination reactions, it is time to return to our discussion of the two mechanisms for elimination. To summarize what we have said so far:

- E1 describes an elimination reaction (E) in which the rate-determining step is unimolecular (1) and does not involve the base. The leaving group leaves in this step, and the proton is removed in a separate second step.

  \[
  \text{general mechanism for E1 elimination} \\
  \text{rate} = k[\text{alkyl halide}]
  \]

- E2 describes an elimination (E) that has a bimolecular (2) rate-determining step that must involve the base. Loss of the leaving group is simultaneous with removal of the proton by the base.

  \[
  \text{general mechanism for E2 elimination} \\
  \text{rate} = k[B^\text{-}][\text{alkyl halide}]
  \]

There are a number of factors that affect whether an elimination goes by an E1 or E2 mechanism. One is immediately obvious from the rate equations: only the E2 is affected by the concentration of base, so at high base concentration E2 is favoured. The rate of an E1 reaction is not even affected by what base is present—so E1 is just as likely with weak as with strong bases, while E2 goes faster with strong bases than weak ones: strong bases at whatever concentration will favour E2 over E1. If you see that a strong base is required for an elimination, it is certainly an E2 reaction. Take the first elimination in this chapter as an example.

\[
\text{reaction of } t\text{-butyl bromide with concentrated hydroxide} \\
\text{HO}^- \quad \text{Br}^- \\
\text{HOH} \quad \text{Br}^-
\]

With less hindered alkyl halides hydroxide would not be a good choice as a base for an elimination because it is rather small and still very good at $S_N2$ substitutions (and even with tertiary alkyl halides, substitution outpaces elimination at low concentrations of hydroxide). So what are good alternatives?
We have already mentioned the bulky t-butoxide—ideal for promoting E2 as it’s both bulky and a strong base ($pK_a$ of t-BuOH = 18). Here it is at work converting a dibromide to a diene with two successive E2 eliminations. Since dibromides can be made from alkenes (you will see how in the next chapter), this is a useful two-step conversion of an alkene to a diene.

The product of the next reaction is a ‘ketene acetal’. Unlike most acetals, this one can’t be formed directly from ketene (ketene, CH$_2$=C=O, is too unstable), so instead the acetal is made by the usual method from bromoacetaldehyde and then HBr is eliminated using t-BuOK.

Among the most commonly used bases for converting alkyl halides to alkenes is one that you met in Chapter 8: DBU. This base is an amidine—delocalization of one nitrogen’s lone pair onto the other, and the resulting stabilization of the protonated amidinium ion, makes it particularly basic, with a $pK_a$ (of the protonated amidine) of about 12.5. There is not much chance of getting those voluminous fused rings into tight corners—so they pick off the easy-to-reach protons rather than attacking carbon atoms in substitution reactions.

DBU will generally eliminate HX from alkyl halides to give alkenes. In these two examples, the products were used as intermediates in the synthesis of natural products.
Substrate structure may allow E1

The first elimination of the chapter (t-BuBr plus hydroxide) illustrates something very important: the starting material is a tertiary alkyl halide and would therefore substitute only by $S_N 1$, but it can eliminate by either E2 (with strong bases) or E1 (with weak bases). The steric factors that disfavour $S_N 2$ at hindered centres don’t exist for eliminations. Nonetheless, E1 can occur only with substrates that can ionize to give relatively stable carbocations—tertiary, allylic, or benzylic alkyl halides, for example. Secondary alkyl halides may eliminate by E1, while primary alkyl halides only ever eliminate by E2 because the primary carbocation required for E1 would be too unstable. The chart below summarizes the types of substrate that can undergo E1—but remember that any of these substrates, under the appropriate conditions (in the presence of strong bases, for example), may also undergo E2. For completeness, we have also included in this chart three alkyl halides that cannot eliminate by either mechanism simply because they do not have any hydrogens to lose from carbon atoms adjacent to the leaving group.

Can a proton just ‘fall off’ a cation?

In E1 mechanisms, once the leaving group has departed almost anything will serve as a base to remove a proton from the intermediate carbocation. Weakly basic solvent molecules (water or alcohols), for example, are quite sufficient, and you will often see the proton just ‘falling off’ in reaction mechanisms, with the assumption that there is a weak base somewhere to capture it. We showed the loss of a proton like this in the last example, and in the chart on this page.

In very rare cases, such as the superacid solutions we described in Chapter 15 (p. 335), the cation is stable because counterions such as $BF_4^-$ and $SbF_6^-$ are not only non-nucleophilic but also so non-basic that they won’t even accept a proton. This fact tells us that despite this common way of writing the E1 mechanism, some sort of weak base is necessary even for E1.
Polar solvents also favour E1 reactions because they stabilize the intermediate carbocation. E1 eliminations from alcohols in aqueous or alcohol solution are particularly common and very useful. An acid catalyst is used to promote loss of water, and in dilute H$_2$SO$_4$, H$_3$PO$_4$, or HCl the absence of good nucleophiles ensures that substitution does not compete. With phosphoric acid, for example, the secondary alcohol cyclohexanol gives cyclohexene.

![Diagram of E1 elimination](image)

But the best E1 eliminations of all are with tertiary alcohols. The alcohols can be made using the methods of Chapter 9: nucleophilic attack by an organometallic on a carbonyl compound. Nucleophilic addition, followed by E1 elimination, is an excellent way of making this substituted cyclohexene, for example. Note that the proton required in the first step is recovered in the last—the reaction requires only catalytic amounts of acid.

Cedrol is important in the perfumery industry—it has a cedar wood fragrance. Corey’s synthesis includes this step—the acid (toluenesulfonic acid, see p. 227) catalyses both the E1 elimination and the hydrolysis of the acetal.

At the end of the last chapter you met some bicyclic structures. These sometimes pose problems for elimination reactions. For example, this compound will not undergo elimination by either an E1 or an E2 mechanism.

![Diagram of bicyclic structure](image)

We shall see shortly what the problem with E2 is, but for E1 the hurdle to be overcome is the formation of a planar carbocation. The bicyclic structure prevents the bridgehead carbon becoming planar so, although the cation would be tertiary, it is very high in energy and does not form. You could say that the non-planar structure forces the cation to have an empty sp$^3$ orbital instead of an empty p orbital, and we saw in Chapter 4 that it is always best to leave the orbitals with the highest possible energy empty.
Bredt’s rule
The impossibility of planar bridgehead carbons means that double bonds can almost never be formed to bridgehead carbons in bicyclic systems. This principle is known as Bredt’s rule, but, as with all rules, it is much more important to know the reason than to know the name, and Bredt’s rule is simply a consequence of the strain induced by a planar bridgehead carbon.

The role of the leaving group
We haven’t yet been very adventurous with our choice of leaving groups for eliminations: all you have seen so far are E2 from alkyl halides and E1 from protonated alcohols. This is deliberate: the vast majority of the two classes of eliminations use one of these two types of starting materials. But since the leaving group is involved in the rate-determining step of both E1 and E2, in general any good leaving group will lead to a fast elimination. You may, for example, see amines acting as leaving groups in eliminations of quaternary ammonium salts.

Eliminations from quaternary ammonium ions

Both E1 and E2 are possible, and from what you have read so far you should be able to spot that there is one of each here: in the first example, a stabilized cation cannot be formed (so E1 is impossible), but a strong base is used, allowing E2. In the second, a stabilized tertiary cation could be formed (so either E1 or E2 might occur), but no strong base is present, so the mechanism must be E1.

You have just seen that hydroxyl groups can be turned into good leaving groups in acid, but this is only useful for substrates that can react by E1 elimination. The hydroxyl group is never a leaving group in E2 eliminations, since they have to be done in base. A strong base would remove the proton from the OH group instead.

- OH⁻ is never a leaving group in an E2 reaction.

For primary and secondary alcohols, the hydroxyl is best made into a leaving group for elimination reactions by sulfonylation with para-toluenesulfonfyl chloride (tosyl chloride, TsCl) or methanesulfonfyl chloride (mesyl chloride, MeSO₂Cl or MsCl).
Toluenesulfonate esters (tosylates) can be made from alcohols (with TsCl, pyridine). We introduced tosylates in Chapter 15 because they are good electrophiles for substitution reactions with non-basic nucleophiles. With strong bases such as t-BuOK, NaOEt, or DBU they undergo very efficient elimination reactions. Here are two examples.

**E2 eliminations of tosylates**

Methanesulfonyl esters (or mesylates; Chapter 15) can be eliminated using DBU, but a good way of using MsCl to convert alcohols to alkenes is to do the mesylation and elimination steps in one go, using the same base (Et₃N) for both. Here are two examples making biologically important molecules. In the first, the mesylate is isolated and then eliminated with DBU to give a synthetic analogue of uracil, one of the nucleotide bases present in RNA. In the second, the mesylate is formed and eliminated in the same step using Et₃N, to give a precursor to a sugar analogue.

The second example here involves (overall) the elimination of a tertiary alcohol—so why couldn’t an acid-catalysed E1 reaction have been used? The problem here, nicely solved by the use of the mesylate, is that the molecule contains an acid-sensitive acetal functional group. An acid-catalysed reaction would also have risked eliminating methanol from the other tertiary centre.

**E1 reactions can be stereoselective**

For some eliminations only one product is possible. For others, there may be a choice of two (or more) alkene products that differ either in the location or stereochemistry of the double bond. We shall now move on to discuss the factors that control the stereochemistry (geometry—*cis* or *trans*) and regiochemistry (that is, where the double bond is) of the alkenes, starting with E1 reactions.
only one alkene possible

two regioisomeric alkenes possible

two stereoisomeric alkenes possible

**E and Z alkenes**

You met the idea that alkenes can exist as geometrical cis and trans isomers in Chapters 3 and 7, and now that you have read Chapter 14 we can be more precise with our definitions. *cis* and *trans* are rather loosely defined terms (like *syn* and *anti*), although no less useful for it. But for formal assignment of geometry, we use the stereochemical descriptors *E* and *Z*. For disubstituted alkenes, *E* corresponds to *trans* and *Z* corresponds to *cis*. To assign *E* or *Z* to tri-or tetrasubstituted alkenes, the groups at either end of the alkene are given an order of priority according to the same rules as those outlined for *R* and *S* in Chapter 15. If the two higher priority groups are *cis*, the alkene is *Z*; if they are *trans* the alkene is *E*. Of course, molecules don’t know these rules, and sometimes (as in the second example here) the *E* alkene is less stable than the *Z*.

*E* alkenes (and transition states leading to *E* alkenes) are usually lower in energy than *Z* alkenes (and the transition states leading to them) for steric reasons: the substituents can get further apart from one another. A reaction that can choose which it forms is therefore likely to favour the formation of *E* alkenes. For alkenes formed by E1 elimination, this is exactly what happens: the less hindered *E* alkene is favoured. Here is an example.

The geometry of the product is determined at the moment that the proton is lost from the intermediate carbocation. The new $\pi$ bond can only form if the vacant p orbital of the carbocation and the breaking C–H bond are aligned parallel. In the example shown there are two possible conformations of the carbocation with parallel orientations, but one is more stable than the other because it suffers less steric hindrance. The same is true of the transition states on the route to the alkenes—the one leading to the *E* alkene is lower in energy, and more *E* alkene than *Z* alkene is formed. The process is stereoselective because the reaction chooses to form predominantly one of two possible stereoisomeric products.
Tamoxifen

Tamoxifen is an important drug in the fight against breast cancer, one of the most common forms of cancer. It works by blocking the action of the female sex hormone oestrogen. The tetrasubstituted double bond can be introduced by an E1 elimination: there is no ambiguity about where the double bond goes, although the two stereoisomers form in about equal amounts. Tamoxifen is the Z isomer.

E1 reactions can be regioselective

We can use the same ideas when we think about E1 eliminations that can give more than one regiosomeric alkene. Here is an example. The major product is the alkene that has the more substituents because this alkene is the more stable of the two possible products.

- More substituted alkenes are more stable.
This is quite a general principle. But why should it be true? The reason for this is related to the reason why more substituted carbocations are more stable. In Chapter 15 we said that the carbocation is stabilized when its empty p orbital can interact with the filled orbitals of parallel C–H and C–C bonds. The same is true of the π system of the double bond—it is stabilized when the empty π* antibonding orbital can interact with the filled orbitals of parallel C–H and C–C bonds. The more C–C or C–H bonds there are, the more stable the alkene.

The more substituted alkene is more stable, but this does not necessarily explain why it is the one that forms faster. To do that, we should look at the transition states leading to the two alkenes. Both form from the same carbocation, but which one we get depends on which proton is lost. Removal of the proton on the right (brown arrow) leads to a transition state in which there is a monosubstituted double bond partly formed. Removal of the proton on the left (orange arrow) leads to a partial double bond that is trisubstituted. This is more stable—the transition state is lower in energy, and the more substituted alkene forms faster.

This explanation of both stereo and regioselectivity in E1 reactions is based on kinetic arguments—which alkene forms faster. But it is also true that some E1 eliminations are reversible: the alkenes may be protonated in acid to re-form carbocations, as you will see in the next chapter. This reprotonation allows the more stable product to form preferentially under thermodynamic control. In any individual case, it may not be clear which is operating. However, with E2 reactions, which follow, only kinetic control applies: E2 reactions are never reversible.
E2 eliminations have anti-periplanar transition states

Although E1 reactions show some stereo and regioselectivity, the level of selectivity in E2 reactions can be much higher because of the more stringent demands on the transition state for E2 elimination. In an E2 elimination, the new \( \pi \) bond is formed by overlap of the \( C-H \) \( \sigma \) bond with the \( C-X \) \( \sigma^* \) antibonding orbital. The two orbitals have to lie in the same plane for best overlap, and now there are two conformations that allow this. One has \( H \) and \( X \) syn-periplanar, the other anti-periplanar. The anti-periplanar conformation is more stable because it is staggered (the syn-periplanar conformation is eclipsed) but, more importantly, only in the anti-periplanar conformation are the bonds (and therefore the orbitals) truly parallel.

E2 eliminations therefore take place preferentially from the anti-periplanar conformation. We shall see shortly how we know this to be the case, but first we consider an E2 elimination that gives mainly one of two possible stereoisomers. 2-Bromobutane has two conformations with \( H \) and \( Br \) anti-periplanar, but the one that is less hindered leads to more of the product, and the \( E \) alkene predominates.

There is a choice of protons to be eliminated—the stereochemistry of the product results from which proton is anti-periplanar to the leaving group when the reaction takes place, and the reaction is stereoselective as a result.

E2 eliminations can be stereospecific

In the next example there is only one proton that can take part in the elimination. Now there is no choice of anti-periplanar transition states. Whether the product is \( E \) or \( Z \), the E2 reaction has only one course to follow. And the outcome depends on which diastereoisomer of the starting material is used. When the first diastereoisomer is drawn with the proton and
bromine anti-periplanar, as required, and in the plane of the page, the two phenyl groups have to lie one in front and one behind the plane of the paper. As the hydroxide attacks the C–H bond and eliminates Br\(^-\), this arrangement is preserved and the two phenyl groups end up \textit{trans} (the alkene is \textit{E}). This is perhaps easier to see in the Newman projection of the same conformation.

The second diastereoisomer forms the \textit{Z} alkene for the same reasons: the two phenyl groups are now on the same side of the H–C–C–Br plane in the reactive anti-periplanar conformation (again, this is clear in the Newman projection) and so they end up \textit{cis} in the product. Each diastereoisomer gives a different alkene geometry, and they do so at different rates. The first reaction is about ten times as fast as the second because, although this anti-periplanar conformation is the only reactive one, it is not necessarily the most stable. The Newman projection for the second reaction shows clearly that the two phenyl groups have to lie synclinal (gauche) to one another: the steric interaction between these large groups will mean that, at any time, a relatively small proportion of molecules will adopt the right conformation for elimination, slowing the process down.

Reactions in which the stereochemistry of the product is determined by the stereochemistry of the starting material are called \textit{stereospecific}.

\textbf{Stereoselective or stereospecific?}

\begin{itemize}
  \item \textbf{Stereoselective reactions} give one predominant product because the reaction pathway has a choice. Either the pathway of lower activation energy is preferred (kinetic control) or the more stable product is preferred (thermodynamic control).
  \item \textbf{Stereospecific reactions} lead to the production of a single isomer as a direct result of the mechanism of the reaction and the stereochemistry of the starting material. There is no choice. The reaction gives a different diastereoisomer of the product from each stereoisomer of the starting material.
\end{itemize}

\textbf{E2 eliminations from cyclohexanes}

The stereospecificity of the reactions you have just met is very good evidence that E2 reactions proceed through an anti-periplanar transition state. We know with which diastereoisomer we started, and we know which alkene we get, so there is no question over the course of the reaction.

More evidence comes from the reactions of substituted cyclohexanes. You saw in Chapter 16 that substituents on cyclohexanes can be parallel with one another only if they are both axial. An equatorial C–X bond is anti-periplanar only to C–C bonds and cannot take part in an elimination. For mono-substituted cyclohexyl halides treated with base, this is not a problem because, although the axial conformer is less stable, there is still a significant amount present (see the table on p. 375), and elimination can take place from this conformer.
For E2 elimination in cyclohexanes, both C–H and C–X must be axial.

These two diastereoisomeric cyclohexyl chlorides derived from menthol react very differently under the same conditions with sodium ethoxide as base. Both eliminate HCl but diastereoisomer A reacts rapidly to give a mixture of products, while diastereoisomer B (which differs only in the configuration of the carbon atom bearing chlorine) gives a single alkene product but very much more slowly. We can safely exclude E1 as a mechanism because the same cation would be formed from both diastereoisomers, and this would mean the ratio of products (although not necessarily the rate) would be the same for both.

\[
\begin{align*}
\text{elimination of diastereoisomer A} & \\
\text{elimination of diastereoisomer B}
\end{align*}
\]

The key to explaining reactions like this is to draw the conformation of the molecules. Both will adopt a chair conformation, and generally the chair having the largest substituent equatorial (or the largest number of substituents equatorial) is the more stable. In these examples the isopropyl group is most influential—it is branched and will have very severe 1,3-diaxial interactions if it occupies an axial position. In both diastereoisomers, an equatorial i-Pr also means an equatorial Me: the only difference is the orientation of the chlorine. For diastereoisomer A, the chlorine is forced axial in the major conformer: there is no choice because the relative configuration is fixed in the starting material. It’s less stable than equatorial Cl, but is ideal for E2 elimination and there are two protons that are anti-periplanar available for removal by the base. The two alkenes are formed as a result of each of the possible protons with a 3:1 preference for the more substituted alkene.

For diastereoisomer B, the chlorine is equatorial in the lowest-energy conformation. Once again there is no choice. But equatorial leaving groups cannot be eliminated by E2: in this conformation there is no anti-periplanar proton. This accounts for the difference in rate between the two diastereoisomers. A has the chlorine axial virtually all the time ready for E2, while B has an axial leaving group only in the minute proportion of the molecules that happen not to be in the lowest-energy conformation, but that have all three substituents axial. The all-axial conformer is much higher in energy, but only in this conformer can Cl\(^{−}\) be eliminated. The concentration of reactive molecules is low, so the rate is also low. There is only one proton anti-periplanar and so elimination gives a single alkene.

\[
\begin{align*}
\text{conformation of diastereoisomer A} & \\
\text{conformation of diastereoisomer B}
\end{align*}
\]
E2 elimination from vinyl halides: how to make alkenes

An anti-periplanar arrangement of C–Br and C–H is attainable with a vinylic bromide too, provided the Br and H are trans to one another. E2 elimination from the Z isomer of a vinyl bromide gives an alkyne rather faster than elimination from the E isomer because in the E isomer the C–H and C–Br bonds are syn-periplanar.

Vinyl bromides can themselves be made by elimination reactions of 1,2-dibromoalkanes. Watch what happens when 1,2-dibromopropane is treated with three equivalents of R₂NLi: first, elimination to the vinyl halide, then elimination of the vinyl halide to the alkyne. The terminal alkyne is amply acidic enough to be deprotonated by R₂NLi, and this is the role of the third equivalent. Overall, the reaction makes a lithiated alkyne (ready for further reactions) from a fully saturated starting material. This may well be the first reaction you have met that makes an alkyne from a starting material that doesn’t already contain a triple bond.

The regioselectivity of E2 eliminations

Here are two deceptively similar elimination reactions. The leaving group changes and the reaction conditions are very different but the overall process is elimination of HX to produce one of two alkenes.

In the first example acid-catalysed elimination of water from a tertiary alcohol produces a trisubstituted alkene. Elimination of HCl from the corresponding tertiary alkyl chloride promoted by a very hindered alkoxide base (more hindered than t-BuOK because all the ethyl groups have to point away from one another) gives exclusively the less stable disubstituted alkene.

The reason for the two different regioselectivities is a change in mechanism. As we have already discussed, acid-catalysed elimination of water from tertiary alcohols is usually E1, and you already know the reason why the more substituted alkene forms faster in E1 reactions (p. 394). It should come as no surprise to you now that the second elimination, with a strong, hindered base, is an E2 reaction. But why does E2 give the less substituted product? This time, there is no problem getting C–H bonds anti-periplanar to the leaving group: in the conformation...
with the Cl axial there are two equivalent ring hydrogens available for elimination, and removal of either of these would lead to the trisubstituted alkene. Additionally, any of the three equivalent methyl hydrogens are in a position to undergo E2 elimination to form the disubstituted alkene whether the Cl is axial or equatorial—and yet it is these and only these that are removed by the hindered base. The diagram summarizes two of the possibilities.

The base attacks the methyl hydrogens because they are less hindered—they are attached to a primary carbon atom, well away from the other axial hydrogens. E2 eliminations with hindered bases typically give the less substituted double bond because the fastest E2 reaction involves deprotonation at the least-substituted site. The hydrogens attached to a less substituted carbon atom are also more acidic. Think of the conjugate bases: a \( t \)-butyl anion is more basic (because the anion is destabilized by the three electron-donating alkyl groups) than a methyl anion, so the corresponding alkane must be less acidic. Steric factors are evident in the following E2 reactions, where changing the base from ethoxide to \( t \)-butoxide alters the major product from the more to the less substituted alkene.

- **Elimination regioselectivity**
  - E1 reactions give the more substituted alkene.
  - E2 reactions may give the more substituted alkene, but become more regioselective for the less substituted alkene with more hindered bases.

**Hofmann and Saytsev**

Traditionally, these two opposite preferences—for the more or the less substituted alkenes—have been called Saytsev’s rule and Hofmann’s rule, respectively. You will see these names used (along with a number of alternative spellings—acceptable for Saytsev, whose name is transliterated from Russian, but not for Hofmann: this Hofmann had one f and two n’s), but there is little point remembering which is which (or how to spell them)—it is far more important to understand the reasons that favour formation of each of the two alkenes.

**Anion-stabilizing groups allow another mechanism—E1cB**

To finish this chapter, we consider a reaction that at first sight seems to go against what we have told you so far. It’s an elimination catalysed by a strong base (KOH), so it looks like E2. But the leaving group is hydroxide, which we categorically (and truthfully) stated cannot be a leaving group in E2 eliminations.

The key to what is going on is the carbonyl group. In Chapter 8 you met the idea that negative charges are stabilized by conjugation with carbonyl groups, and the list on p. 176 demonstrated how acidic a proton adjacent to a carbonyl group is. The proton that is removed in this elimination reaction is adjacent to the carbonyl group, and is therefore also rather acidic (\( pK_a \) about 20). This means that the base can remove it without the leaving group departing at the
same time—the anion that results is stable enough to exist because it can be delocalized on to the carbonyl group.

Although the anion is stabilized by the carbonyl group, it still prefers to lose a leaving group and become an alkene. This is the next step.

This step is also the rate-determining step of the elimination—the elimination is unimolecular and so is some kind of E1 reaction. The leaving group is not lost from the starting molecule, but from the conjugate base of the starting molecule, so this sort of elimination, which starts with a deprotonation, is called E1cB (cB for conjugate base). Here is the full mechanism, generalized for other carbonyl compounds.

It’s important to note that, while \( \text{HO}^- \) is never a leaving group in E2 reactions, it can be a leaving group in E1cB reactions. The anion it is lost from is already an alkoxide—the oxy-anion does not need to be created as the \( \text{HO}^- \) is lost. The establishment of conjugation in the product also assists loss of \( \text{HO}^- \). As the scheme above implies, other leaving groups are possible too. Here are two examples with methanesulfonate leaving groups.

The first looks E1 (stabilized cation), the second E2—but in fact both are E1cB reactions. The most reliable way to spot a likely E1cB elimination is to see whether the alkene in the product is conjugated with a carbonyl group. If it is, the mechanism is probably E1cB.

\( \beta \)-Halocarbonyl compounds can be rather unstable: the combination of a good leaving group and an acidic proton means that E1cB elimination is extremely easy. This mixture of diastereoisomers is first of all lactonized in acid (Chapter 10), and then undergoes E1cB
elimination with triethylamine to give a product known as a butenolide. Butenolides are common structures in naturally occurring compounds.

You will have noticed that we have shown the deprotonation step in the last few mechanisms as an equilibrium. Both equilibria lie rather over to the left-hand side because neither triethylamine (pKₐ of Et₃NH⁺ about 10) nor hydroxide (pKₐ of H₂O 15.7) is basic enough to remove completely a proton next to a carbonyl group (pKₐ > 20). However, because the loss of the leaving group is essentially irreversible, only a small amount of deprotonated carbonyl compound is necessary to keep the reaction going. The important point about substrates that undergo E1cB is that there is some form of anion-stabilizing group next to the proton to be removed—it doesn’t have to stabilize the anion very well but, as long as it makes the proton more acidic, an E1cB mechanism has a chance. Here is an important example with two phenyl rings helping to stabilize the anion, and a carbamate anion (R₂N—CO₂⁻) as the leaving group.

The proton to be removed has a pKₐ of about 25 because its conjugate base is an aromatic cyclopentadienyl anion (we discussed this in Chapter 8). The E1cB elimination takes place with a secondary or tertiary amine as the base. Spontaneous loss of CO₂ from the eliminated product gives an amine, and you will meet this class of compounds again in Chapter 23, where we discuss the Fmoc protecting group.

The E1cB rate equation
The rate-determining elimination step in an E1cB reaction is unimolecular, so you might imagine it would have a first-order rate equation. In fact, the rate is also dependent on the concentration of base. This is because the unimolecular elimination involves a species—the anion—whose concentration is itself determined by the concentration of base by the equilibrium we have just been discussing. Using the following general E1cB reaction, the concentration of the anion can be expressed as shown.
The rate is proportional to the concentration of the anion, and we now have an expression for that concentration. We can simplify it further because the concentration of water is effectively constant.

\[
rate = k \frac{K}{[\text{H}_2\text{O}]} \left[ \frac{\text{RO}^+ \text{OH}}{[\text{RO}^+ \text{OH}]} \right] = \text{constant} \times \left[ \frac{\text{RO}^+ \text{OH}}{[\text{RO}^+ \text{OH}]} \right] \]

Just because the base (hydroxide) appears in this rate equation doesn’t mean to say it is involved in the rate-determining step. Increasing the concentration of base makes the reaction go faster by increasing the amount of anion available to eliminate.

**E1cB eliminations in context**

We can also compare the E1cB mechanism with the other elimination reactions you have met by thinking of the relative timing of proton removal and leaving group departure. E1 is at one end of the scale: the leaving group goes first and proton removal follows in a second step. In E2 reactions, the two events happen at the same time: the proton is removed as the leaving group leaves. In E1cB the proton removal moves in front of leaving group departure.

We talked about regio- and stereoselectivity in connection with E1 and E2 reactions. With E1cB, the regioselectivity is straightforward: the location of the double bond is defined by the position of (a) the acidic proton and (b) the leaving group.

E1cB reactions may be stereoselective—the one above, for example, gives mainly the \( E \) alkene product (2:1 with \( Z \)). The intermediate anion is planar, so the stereochemistry of the starting materials is irrelevant, the less sterically hindered (usually \( E \)) product is preferred. This double E1cB elimination, for example, gives only the \( E, E \) product.
To finish this chapter we need to tell you about two E1cB eliminations that you may meet in unexpected places. We have saved them till now because they are unusual in that the leaving group is actually part of the anion-stabilizing group itself. First of all, try spotting the E1cB elimination in this step from the first total synthesis of penicillin V.

\[
\begin{align*}
\text{HN} & \quad \text{S} \\
\text{CO}_2\text{H} & \quad \text{Me} \\
\text{Me} & \quad \text{Cl} \\
\text{PhO} & \quad \text{O} \\
\text{t-BuO}_2\text{C} & \quad \text{NH}_2 \\
\text{Et}_3\text{N} \quad \text{HN} & \quad \text{S} \\
\text{CO}_2\text{H} & \quad \text{Me} \\
\text{Me} & \quad \text{t-BuO}_2\text{C} \\
\text{PhO} & \quad \text{O} \\
\text{several steps} \quad \text{penicillin V} 
\end{align*}
\]

The reaction is deceptively simple—formation of an amide in the presence of base—and you would expect the mechanism to follow what we told you in Chapter 10. But the acyl chloride is, in fact, set up for an E1cB elimination—and you should expect this whenever you see an acyl chloride with acidic protons next to the carbonyl group used in the presence of a base such as triethylamine.

The product of the elimination is a substituted ketene—a highly reactive species whose parent structure is the molecule \( \text{CH}_2=\text{C}=\text{O} \) that you will meet in the next chapter. It is the ketene that reacts with the amine to form the amide.

The second ‘concealed’ E1cB elimination is disguised in the mechanism of formation of methanesulfonates (mesylates). When we introduced sulfonate esters in Chapter 15, and revisited them on p. 391 of this chapter, we avoided (uncharacteristically, you may say) explaining the mechanism by which they are formed from sulfonyl chlorides. This was deliberate because, while \( \text{TsCl} \) reacts with alcohols by the mechanism you might predict, the reaction with \( \text{MsCl} \) involves an elimination step.

Here is the mechanism by which alkyl tosylates are formed from alcohols. The alcohol acts as a nucleophile towards the electrophilic sulfonyl chloride, and pyridine removes a proton to give the product.

\[
\begin{align*}
\text{formation of toluenesulfonates (tosylates): reagents ROH + TsCl + pyridine} \\
\end{align*}
\]

Methanesulfonyl chloride by contrast has a feature it shares with the acyl chlorides just above: a relatively acidic proton that can be removed by base. This deprotonation, followed by loss of chloride, is the first step in the formation of a mesylate ester. It is an E1cB elimination and the product is called a sulfene.
The sulfene is electrophilic in a slightly odd way: the alcohol acts as a nucleophile for sulfur and generates an anion of carbon which undergoes a proton transfer to give the mesylate. It is not uncommon for anions to form adjacent to sulfur, as you will see again in Chapter 27. Notice how similar the overall mechanism is to the acylation mechanism we showed you above.

**To conclude**

We finish with brief summaries of three important discussions we have had in this chapter.

**Elimination versus substitution**

The table below summarizes the general pattern of reactivity expected from various structural classes of alkyl halides (or tosylates, mesylates) in reactions with a representative range of nucleophiles (which may behave as bases).

</tbody>
</table>
Some points about the table:

- Methyl halides cannot eliminate as there are no appropriately placed protons.
- Increasing branching favours elimination over substitution and strongly basic hindered nucleophiles always eliminate unless there is no option.
- Good nucleophiles undergo substitution by S_N2 unless the substrate is tertiary and then the intermediate cation can eliminate by E1 as well as substitute by S_N1.
- High temperatures favour elimination by gearing up the importance of entropy in the free energy of reaction \(\Delta G = \Delta H - T\Delta S\). This is a good way of ensuring E1 in ambiguous cases.

**Summary of the stabilities of types of alkene**

Alkenes are stabilized by:

- **conjugation**—anything that can conjugate with an alkene stabilizes it, including carbonyl groups, nitriles, benzene rings, RO or RNH groups, or another alkene. This is the strongest stabilization and usually dominates.

- **substitution**—alkyl groups stabilize alkenes weakly by \(\sigma\)-conjugation, so the more alkyl groups the better—but beware of the next point.

- **lack of steric hindrance**—as alkenes are planar, large, especially branched, substituents arranged syn on the alkene destabilize it, so tetra-substituted alkenes are usually less stable than tri-substituted ones. If the alkene is in a stable ring, this does not apply as the ring substituents have to be syn for the ring to exist.

**Alkene stereochemistry: a summary of terminology**

The official way of assigning alkene geometry is \(E\) and \(Z\). \(Z\) comes from the German zusammen (together) and means that the two highest ranking substituents (by the same rules introduced in Chapter 14 for \(R\) and \(S\)) are on the same side of the alkene. The letter \(Z\) is a particularly unfortunate choice as it looks like a \(trans\) alkene! \(E\) comes from the German entgegen (opposed) and means that the two highest ranking substituents are on opposite sides (and, if anything also unfortunately looks like a \(cis\) alkene). The green numbers in the structures below show the relative rankings of the two substituents at each end of the alkene and the consequent assignment of geometry.

![Structures showing \(E\) and \(Z\) configurations](image)

But possibly the most common method of referring to alkene geometry is to use \(cis\) and \(trans\). These require a diagram as they refer to two substituents being on the same (\(cis\)) or opposite (\(trans\)) sides of the alkene. There is no specified order of priority and the speaker chooses substituents that are significant to the structure or to the reaction under discussion, making this a more flexible and versatile way of talking about alkenes. We have assigned \(cis\) and \(trans\) to the alkenes above to indicate their most important features, but notice the ambiguities that may occur.

- This terminology may be used only for alkenes and not for three-dimensional stereochemistry.
- Much the same are the terms \(syn\) and \(anti\), introduced on p. 317 and used for relative three-dimensional stereochemistry. There is no formal definition, and a diagram is needed for clarity.

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Review of spectroscopic methods

This is the first of two review chapters on spectroscopic methods taken as a whole. In Chapter 31 we shall tackle the complete identification of organic compounds, including the vital aspect of stereochemistry, introduced in Chapters 14 and 17. In this chapter we gather together some of the ideas introduced in previous chapters on spectroscopy and mechanism, and show how they are related. We shall explain the structure of the chapter as we go along.

There are three reasons for this chapter

1. To review the methods of structure determination we met in Chapters 3 and 13, to extend them a little further, and to consider the relationships between them.
2. To show how these methods may be combined to determine the structure of unknown molecules.
3. To provide useful tables of data for you to use when you are attempting to determine unknown structures.

The main tables of data appear at the end of the chapter (pp. 423–425) so that they are easy to refer to when you are working on problems. You may also wish to look at them, along with the tables in the text, as you work through this chapter.

We shall deal with points 1 and 2 together, looking first at the interplay between the chemistry of the carbonyl group (as discussed in Chapters 10 and 11) and spectroscopy, solving some structural problems, then moving on to discuss, for example, NMR of more...
than one element in the same compound, doing some more problems, and so on. We hope that the lessons from each section will help in your overall understanding of structure solving. The first section deals with the assignment of carbonyl compounds to their various classes.

**Spectroscopy and carbonyl chemistry**

Chapters 10 and 11 completed our systematic survey of carbonyl chemistry, and we can now put together chemistry and spectroscopy on this most important of all functional groups.

We have divided carbonyl compounds into two main groups:

1. **aldehydes** (RCHO) and **ketones** (R¹COR²)
2. **acids** (RCO₂H) and their derivatives (in order of reactivity):
   - **acid chlorides** (RCOCl)
   - **anhydrides** (RCO₂COR)
   - **esters** (R¹CO₂R²)
   - **amides** (RCONH₂, R¹CONMe₂, etc.).

Which spectroscopic methods most reliably distinguish these two groups? Which help us to separate aldehydes from ketones? Which allow us to distinguish the various acid derivatives? Which offer the most reliable evidence on the chemistry of the carbonyl group? These are the questions we tackle in this section.

**Distinguishing aldehydes and ketones from acid derivatives**

The most consistently reliable method for doing this is ¹³C NMR. It doesn’t much matter whether the compounds are cyclic or unsaturated or have aromatic substituents, they all give carbonyl ¹³C shifts in about the same regions. There is a selection of examples on the facing page which we now discuss. First, look at the shifts arrowed into the carbonyl group on each structure. All the aldehydes and ketones fall between 191 and 208 ppm regardless of structure, whereas all the acid derivatives (and these are very varied indeed!) fall between 164 and 180 ppm. These two sets do not overlap and the distinction is easily made. Assigning the spectrum of the ketoacid in the margin, for example, is easy.

> ¹³C NMR distinguishes acid derivatives from aldehydes and ketones

The carbonyl carbons of all aldehydes and ketones resonate at about 200 ppm, while acid derivatives usually resonate at about 175 ppm.

More on these structures

Aldehydes and ketones

The first aldehyde is vanillin, which comes from the vanilla pod and gives the characteristic vanilla flavour in, for example, ice cream. Vanilla is the seed pod of a South American orchid. 'Vanilla essence' is made with synthetic vanillin and tastes slightly different because the vanilla pod contains other flavour components in small quantities. The second aldehyde is retinal. As you look at this structure your eyes use the light reaching them to interconvert cis and trans retinal in your retina to create nervous impulses (see also Chapter 27).

The two ketones are all flavour compounds too. The first, (–)-carvone, is the chief component (70%) of spearmint oil. Carvone is an interesting compound: in Chapter 14 you met the mirror-image isomers known as enantiomers, and (–)-carvone’s mirror image, (+)-carvone, is the chief component (35%) of dill oil. Our taste can tell the difference, although an NMR machine can’t and both carvones have identical NMR spectra. See Chapter 14 for more detail! The second ketone is ‘raspberry ketone’, which is largely responsible for the flavour of raspberries. It is entirely responsible for the flavour of some ‘raspberry’ foods. The signal for the aromatic carbon joined to OH is at 154.3 ppm (in the 100–150 ppm region because it is an unsaturated carbon atom joined to oxygen) and cannot possibly be confused with the ketone signal at 208.8 ppm. Both ketones have C=O shifts at about 200 ppm, and both lack any signals in the proton NMR of δ > 8.

Acid derivatives

Lipoic acid uses its S–S bond in redox reactions (Chapter 42), while shikimic acid is an intermediate in the formation of compounds with benzene rings, such as phenylalanine, in living things (Chapter 42). Salicylic acid’s acetate ester is aspirin, which is, of course, like the last example ibuprofen, a painkiller.

The first acid chloride is a popular reagent for the synthesis of acetate esters and you have seen its reactions in Chapter 10. We have chosen three cyclic anhydrides as examples because they are all related to an important reaction (the Diels–Alder reaction), which you will meet in Chapter 34.

The first ester, methyl methacrylate, is a bulk chemical. It is the monomer whose polymerization gives Perspex, the rigid transparent plastic used in windows and roofs. The second ester is an important local anaesthetic used for minor operations.

One amide is the now-familiar DMF, but the other is a tetrapeptide and so contains one carboxylic acid group at the end and three amide groups. Although the four amino acids in this peptide are identical (alanine, Ala for short), the carbon NMR faithfully picks up four different C=O signals, all made different by being different distances from the end of the chain.
The distinction can be vital in structural problems. The symmetrical alkyne diol below cyclizes in acid with Hg(II) catalysis to a compound having, by proton NMR, the structural fragments shown. The product is unsymmetrical in that the two CMe₂ groups are still present, but they are now different. In addition, the chemical shift of the CH₂ group shows that it is next to C=O but not next to oxygen. This leaves us with two possible structures. One is an ester and one a ketone. The C=O shift is 218.8 ppm and so there is no doubt that the second structure is correct.

Distinguishing aldehydes from ketones is simple by proton NMR

Now look at the first two groups, the aldehydes and ketones. The two aldehydes have smaller carbonyl shifts than the two ketones, but they are too similar for this distinction to be reliable. What distinguishes the aldehydes very clearly is the characteristic proton signal for CHO at 9–10 ppm. So you should identify aldehydes and ketones by C=O shifts in carbon NMR and then separate the two by proton NMR.

Distinguishing acid derivatives by carbon NMR is difficult

Now examine the other panels on p. 409. The four carboxylic acids are all important biologically or medicinally. Their C=O shifts are very different from each other as well as from those of the aldehydes or ketones.

The next five compounds (two acid chlorides and three anhydrides) are all reactive acid derivatives, and the five esters and amides below them are all unreactive acid derivatives and yet the C=O shifts of all ten compounds fall in the same range. The C=O chemical shift is obviously not a good way to check on chemical reactivity.

What the carbon NMR fails to do is distinguish these types of acid derivative. There is more variation between the carboxylic acids on display than between the different classes of acid derivatives. This should be obvious if we show you some compounds containing two acid derivatives. Would you care to assign these signals?

No, neither would we. In each case the difference between the carbonyl signals is only a few ppm. Although acid chlorides are extremely reactive in comparison with esters or amides, the electron deficiency at the carbon nucleus as measured by deshielding in the NMR spectrum evidently does not reflect this. Carbon NMR reliably distinguishes acid derivatives as a group from aldehydes and ketones as another group but it fails to distinguish even very reactive (for
Acid derivatives are best distinguished by infrared

A much better measure is the difference in IR stretching frequency of the C=O group. We discussed this in Chapter 10 (p. 206), where we noted a competition between conjugation by lone-pair electron donation into the carbonyl from OCOR, OR, or NH₂ and inductive withdrawal from the C=O group because of the electronegativity of the substituent. Conjugation donates electrons into the π* orbital of the π bond and so lengthens and weakens it. The C=O bond becomes more like a single bond and its stretching frequency moves towards the single-bond region, that is, it goes down. The inductive effect removes electrons from the π orbital and so shortens and strengthens the π bond. It becomes more like a full double bond and moves up in frequency.

These effects are balanced in different ways according to the substituent. Chlorine is poor at lone-pair electron donation (its lone pair is in a large 3p orbital and overlaps badly with the 2p orbital on carbon) but strongly electron-withdrawing so acid chlorides absorb at high frequency, almost in the triple-bond region. Anhydrides have an oxygen atom between two carbonyl groups. Inductive withdrawal is still strong but conjugation is weak because the lone pairs are pulled both ways. Esters have a well-balanced combination with the inductive effect slightly stronger (oxygen donates from a compatible 2p orbital but is very electronegative and so withdraws electrons strongly as well). Finally, amides are dominated by conjugation as nitrogen is a much stronger electron donor than oxygen because it is less electronegative.

Conjugation with π electrons or lone pairs affects IR C=O stretches

We need to see how conjugation works when it is with a π bond rather than with a lone pair. This will make the concept more general as it will apply to aldehydes and ketones as well as to acid groups. How can we detect whether an unsaturated carbonyl compound is conjugated or not? Well, compare these two unsaturated aldehydes.
The key differences are the frequency of the C=O stretch (lowered by 40 cm⁻¹ by conjugation) and the strength (that is, the intensity) of the C=C stretch (increased by conjugation) in the IR. In the ¹³C NMR, C3 in the conjugated enal is moved out of the alkene region just into the carbonyl region, showing how electron-deficient this carbon atom must be. In the proton NMR there are many effects but the downfield shift of the protons on the alkene, especially C3 (again!), is probably the most helpful.

Because the infrared carbonyl frequencies follow such a predictable pattern, it is possible to make a simple list of correlations using just three factors. Two are the ones we have been discussing—conjugation (frequency-lowering) and the inductive effect (frequency-raising). The third is the effect of small rings and this we next need to consider in a broader context.

**Small rings introduce strain inside the ring and higher s character outside it**

Cyclic ketones can achieve the perfect 120° angle at the carbonyl group only if the ring is at least six-membered. The smaller rings are ‘strained’ because the orbitals have to overlap at a less than ideal angle.

For a four-membered ring, the actual angle is 90°, so there is 120° − 90° = 30° of strain at the carbonyl group. The effects of this strain on five-, four-, and three-membered rings are shown here.
But why should strain raise the frequency of a carbonyl group? It is evidently shortening and strengthening the C=O bond as it moves it towards the triple-bond region (higher frequency), not towards the single-bond region (lower frequency). In a six-membered ring, the sp² orbitals forming the σ framework around the carbonyl group can overlap perfectly with the sp³ orbitals on neighbouring carbon atoms because the orbital angle and the bond angle are the same. In a four-membered ring the orbitals do not point towards those on the neighbouring carbon atoms, but point too far out, effectively forcing the bonds to be bent and lowering the degree of overlap.

Ideally, we should like the orbitals to have an angle of 90° as this would make the orbital angle the same as the bond angle. In theory it would be possible to have a bond angle of 90° if we used pure p orbitals instead of sp² hybrid orbitals. The diagram in the margin shows this hypothetical situation. If we did this, we should leave a pure s orbital for the σ bond to oxygen. This extreme is not possible, but a compromise is. Some more p character goes into the ring bonds—maybe they become s°p³—so that they can approach the 90° angle needed, and the same amount of extra s character goes into the σ bond to oxygen. The more s character there is in the orbital, the shorter it gets as s orbitals are much smaller than p orbitals.

**Simple calculations of C=O stretching frequencies in IR spectra**

The best way is to relate all our carbonyl frequencies to those for saturated ketones (1715 cm⁻¹). We can summarize what we have just learned in a table.

Notice in this simple table (for full details you should refer as usual to a specialist book) that the adjustment ‘30 cm⁻¹’ appears quite a lot (~30 cm⁻¹ for both alkene and aryl, for example), that the increment for small rings is 35 cm⁻¹ each time (30 to 65 cm⁻¹ and then 65 to 100 cm⁻¹), and that the extreme effects of Cl and NH₂ are +85 and ~85 cm⁻¹, respectively. These effects are additive. If you want to estimate the C=O frequency of a proposed structure, just add or subtract all the adjustments to 1715 cm⁻¹ and you will get a reasonable result.

*Difference between stretching frequency of C=O and stretching frequency of a typical saturated ketone (1715 cm⁻¹).*
Try this out with the five-membered unsaturated (and conjugated) lactone (cyclic ester) in the margin. We must add 30 cm\(^{-1}\) for the ester, subtract 30 cm\(^{-1}\) for the double bond, and add 30 cm\(^{-1}\) for the five-membered ring. Two of those cancel out, leaving just 1715 + 30 = 1745 cm\(^{-1}\). These compounds absorb at 1740–1760 cm\(^{-1}\). Not bad!

**NMR spectra of alkynes and small rings**

This idea that small rings have more p character in the ring and more s character outside the ring also explains the effects of small rings on proton NMR shifts. These hydrogens, particularly on three-membered rings, resonate at unusually high fields, between 0 and 1 ppm in cyclopropanes instead of the 1.3 ppm expected for CH\(_2\) groups, and may even appear at negative \(\delta\) values. High p character in the framework of small rings also means high s character in C–H bonds outside the ring and this will mean shorter bonds, greater shielding, and small \(\delta\) values.

### Three-membered rings and alkynes

You have also seen the same argument used in Chapter 8 to justify the unusual acidity of C–H protons on triple bonds (such as alkynes and HCN), and alluded to in Chapter 3 to explain the stretching frequency of the same C–H bonds. Like alkynes, three-membered rings are also unusually easy to deprotonate in base. Here is an example where deprotonation occurs at a different site in two compounds identical except for a C–C bond closing a three-membered ring. The first is an ortholithiation of the type discussed in Chapter 24.

Now what about the NMR spectra of alkynes? By the same argument, protons on alkynes ought to appear in the NMR at quite high field because the C atom is sp hybridized, so it makes its \(\sigma\) bonds with sp orbitals (i.e. 50% s character). Protons on a typical alkene have \(\delta_H\) about 5.5 ppm, while the proton on an alkyne comes right in the middle of the protons on saturated carbons at about \(\delta_H\) 2–2.5 ppm. This is rather a large effect just for increased s character and some of it is probably due to better shielding by the triple bond, which surrounds the linear alkyne with \(\pi\) bonds without a nodal plane.

This means that the carbon atoms also appear at higher field than expected, not in the alkene region but from about \(\delta_C\) 60–80 ppm. The s character argument is important, however, because shielding can’t affect IR stretching frequencies, yet C≡C–H stretches are strong and at about 3300 cm\(^{-1}\), just right for a strong C–H bond.

A simple example is the ether 3-methoxyprop-1-yne. Integration alone allows us to assign the spectrum and the 1H signal at 2.42 ppm, the highest field signal, is clearly the alkyne proton. Notice also that it is a triplet and that the OCH\(_2\) group is a doublet. This \(J_{HH}\) is small (about 2 Hz) and, although there is nothing like a letter ‘W’ in the arrangement of the bonds, coupling of this kind is often found in alkynes.
A more interesting example comes from the base-catalysed addition of methanol to buta-1,3-diyne (diacetylene). The compound formed has one double and one triple bond and the $^{13}$C NMR shows clearly the greater deshielding of the double bond.

You may have noticed that we have drawn the double bond with the cis (Z) configuration. We know that this is true because of the proton NMR, which shows a 6.5 Hz coupling between the two alkene protons (much too small for a trans coupling; see p. 295). There is also the longer-range coupling ($^2J = 2.5$ Hz) just described and even a small very long-range coupling ($^5J = 1$ Hz) between the alkyne proton and the terminal alkene proton.

**Proton NMR distinguishes axial and equatorial protons in cyclohexanes**

Coupling is a through-bond phenomenon, as we know from the couplings in cis and trans alkenes, where trans alkenes have much larger coupling constants as their orbitals are perfectly parallel. Another case of perfectly parallel orbitals occurs with trans-diaxial protons in cyclohexanes. Typical coupling constants are 10–12 Hz for trans-diaxial protons, but much smaller (2–5 Hz) for axial/equatorial and equatorial/equatorial protons.

This makes assignment of conformation easy. The simple ester below has a triple triplet for the black H, with two large coupling constants (8.8 Hz) that must be to axial protons (green) and two small coupling constants (3.8 Hz) that must be to equatorial Hs (brown). This is possible only if the black H is axial and the ester group must therefore be equatorial. The acetal ester on the right is very different: it is a simple triplet with two small coupling constants (3.2 Hz), which is too small for an axial/axial coupling. The only possibility therefore is that the black proton is equatorial, and one of the 3.2 Hz couplings is to its equatorial neighbour, and the other to its axial neighbour. The ester group must be axial in this compound.

**Interactions between different nuclei can give enormous coupling constants**

We have looked at coupling between hydrogen atoms and you may have wondered why we have ignored coupling between other NMR active nuclei. Why does $^{13}$C not cause similar couplings? In this section we are going to consider not only couplings between the same kind of nuclei,
such as two protons, called **homonuclear coupling**, but also coupling between different nuclei, such as a proton and a fluorine atom or $^{13}$C and $^{31}$P, called **heteronuclear coupling**.

Two nuclei are particularly important, $^{19}$F and $^{31}$P, since many organic compounds contain these elements and both are at essentially 100% natural abundance and have spin $I = 1/2$. We shall start with organic compounds that have just one of these nuclei and see what happens to both the $^1$H and the $^{13}$C spectra. In fact, it is easy to find a $^{19}$F or a $^{31}$P atom in a molecule because these elements couple to all nearby carbon and hydrogen atoms. Since they can be directly bonded to either, $^1J$ coupling constants such as $^1J_{CF}$ or $^1J_{PH}$ become possible, as well as the more ‘normal’ couplings such as $^2J_{CF}$ or $^2J_{PH}$, and these $^1J$ coupling constants can be enormous.

We shall start with a simple phosphorus compound, the dimethyl ester of phosphorous acid (H$_3$PO$_3$). There is an uncertainty about the structure of both the acid and its esters. They could exist as $P$(III) compounds with a lone pair of electrons on phosphorus, or as $P$(V) compounds with a $P$=$O$ double bond.

In fact, dimethyl phosphite has a $^1$H doublet with the amazing coupling constant of 693 Hz: on a 250 MHz machine the two lines are over 2 ppm apart and it is easy to miss that they are two halves of the same doublet. This can only be a $^1J_{PH}$ as it is so enormous. The compound has to have a $P$–$H$ bond and the $P$(V) structure is correct. The coupling to the protons of the methyl group is much smaller but still large for a three-bond coupling ($^3J_{PC}$ of 18 Hz).

Next, consider the phosphonium salt you met at the end of Chapter 11 for use in the Wittig reaction, turning aldehydes and ketones to alkenes. It has a $^2J_{PH}$ of 18 Hz. There is no doubt about this structure—it is just an illustration of coupling to phosphorus. There is coupling to phosphorus in the carbon spectrum too: the methyl group appears at $\delta$C 10.6 ppm with a $^1J_{PC}$ of 57 Hz, somewhat smaller than typical $^2J_{PH}$. We haven’t yet talked about couplings to $^{13}$C: we shall now do so.

**Coupling in carbon NMR spectra**

We shall use coupling with fluorine to introduce this section. Fluorobenzenes are good examples because they have a number of different carbon atoms all coupled to the fluorine atom.

The carbon directly joined to fluorine (the **ipso** carbon) has a very large $^1J_{CF}$ value of about 250 Hz. More distant coupling is evident too: all the carbons in the ring couple to the fluorine in PhF with steadily diminishing $^1J$ values as the carbons become more distant.

Trifluoroacetic acid is an important strong organic acid (Chapter 8) and a good solvent for $^1$H NMR. The carbon atom of the CF$_3$ group is coupled equally to all the three fluorines and so appears as a quartet with a large $^1J_{CF}$ of 283 Hz, about the same as in PhF. Even the carbonyl
The group is also a quartet, although the coupling constant is much smaller ($J_{CF}$ is 43 Hz). Notice too how far downfield the CF$_3$ carbon atom is!

### 13C NMR spectrum

50 MHz

trifluoroacetic acid

283 Hz

### Coupling between protons and 13C

In view of all this, you may ask why we don’t apparently see couplings between 13C and 1H in either carbon or proton spectra. In proton spectra the answer is simple: we don’t see coupling to 13C because of the low abundance (1.1%) of 13C. Most protons are bonded to 12C: only 1.1% of protons are bonded to 13C. If you look closely at proton spectra with very flat baselines, you may see small peaks either side of strong peaks at about 0.5% peak height. These are the 13C ‘satellites’ for those protons that are bonded to 13C atoms.

As an example, look again at the 500 MHz 1H NMR spectrum of heptan-2-one that we saw on p. 294. When the baseline of this spectrum is vertically expanded, the 13C satellites may be seen. The singlet due to the methyl protons is actually in the centre of a tiny doublet due to the 1% of protons coupling to 13C. Similarly, each of the triplets in the spectrum is flanked by two tiny triplets. The two tiny triplets on either side make up a doublet of triplets with a large $J_{CH}$ coupling constant to the 13C (around 130 Hz) and smaller $J_{CH}$ coupling to the two equivalent protons.

13C satellites are usually lost in the background noise of the spectrum and need concern us no further. You do, however, see coupling in the 1H NMR spectrum with compounds deliberately labelled with 13C because the 13C abundance can then approach 100%. The same Wittig reagent we saw a moment ago shows a 3H doublet of doublets with the typically enormous $J_{CH}$ of 135 Hz when labelled with pure 13C in the methyl group.

$\delta_H$ 3.25 (3H, dd, $J_{CH}$ 135, $J_{FH}$ 18 Hz)
But this begs the question—where is the 135 Hz coupling in the $^{13}$C NMR? Surely we should see this coupling to the protons in the $^{13}$C NMR spectrum too?

**Why is there no coupling consistently seen in carbon spectra?**

We get the singlets consistently seen in carbon spectra because of the way we record the spectra. The values of $^{1}$J$_{CH}$ are so large that, if we recorded $^{13}$C spectra with all the coupling constants, we would get a mass of overlapping peaks. When run on the same spectrometer, the frequency at which $^{13}$C nuclei resonate turns out to be about a quarter of that of the protons. Thus a 400 MHz machine (remember that the magnet strength is usually described by the frequency at which the protons resonate) gives $^{13}$C spectra at 100 MHz. Coupling constants ($^{1}$J$_{CH}$) of 100–250 Hz would cover 2–5 ppm and a CH$_3$ group with $^{1}$J$_{CH}$ of about 125 Hz would give a quartet covering nearly 8 ppm (see the example on the previous page).

Since the proton-coupled $^{13}$C spectrum can so easily help us to distinguish CH$_3$, CH$_2$, CH, and quaternary carbons, you might wonder why they are not used more. The above example was chosen very carefully to illustrate proton-coupled spectra at their best. Unfortunately, this is not a typical example. More usually, the confusion from overlapping peaks makes this just not worthwhile. So $^{13}$C NMR spectra are recorded while the whole 10 ppm proton spectrum is being irradiated with a secondary radio frequency source. The proton energy levels are equalized by this process and all coupling disappears. Hence the singlets we are used to seeing.

For the rest of this chapter we shall not be introducing new theory or new concepts; we shall be applying what we have told you to a series of examples where spectroscopy enables chemists to identify compounds.

**Identifying products spectroscopically**

**An ambiguous reaction product**

In Chapter 3 we gave an example of a compound which was misidentified because an O atom and an N atom were mistaken for one another, even in the X-ray crystal structure.
Another famous case of ambiguity between structures containing O or N arises in the identification of the product of addition of hydroxylamine (NH$_2$OH) to a simple enone. This condensation reaction gives a compound with the formula C$_6$H$_{11}$NO. But what is its structure? We can first of all think about what we expect to happen: it is not always necessary to do this in order to identify a structure, but it can help. Nitrogen is more nucleophilic than oxygen so we might expect it to add first. But will it add directly to the carbonyl group or in the conjugate fashion we shall describe in Chapter 22? Either way, an intermediate will be formed that can cyclize.

The two possible isomeric products were once the subject of a long-running controversy, but with IR and proton NMR spectra of the product, doubt vanished. The IR showed no NH stretch. The NMR showed no alkene proton but did have a CH$_2$ group at 2.63 ppm. Only the second structure is possible.

We need to look now at a selection of problems of different kinds to show how the various spectroscopic methods can cooperate in structure determination.

**Reactive intermediates can be detected by spectroscopy**

Some intermediates proposed in reaction mechanisms look so unlikely that it is comforting if they can be isolated and their structure determined. We feel more confident in proposing an intermediate if we are sure that it can really be made. Of course, this is not necessarily evidence that the intermediate is actually formed during reactions and it certainly does not follow that the failure to isolate a given intermediate disproves its involvement in a reaction. We shall use ketene as an example.

Ketene looks pretty unlikely! It is CH$_2$=C=O with two π bonds (C=C and C=O) to the same carbon atom. The orbitals for these π bonds must be orthogonal because the central carbon atom is sp hybridized with two linear σ bonds and two p orbitals at right angles both to the σ bonds and to each other. Can such a molecule exist? When acetone vapour is heated to very high temperatures (700–750 °C) methane is given off and ketene is supposed to be the other product. What is isolated is a ketene dimer (C$_4$H$_4$O$_2$) and even the structure of this is in doubt as two reasonable structures can be written.

The spectra fit the ester structure well, but not the more symmetrical diketone structure at all. There are three types of proton (cyclobuta-1,3-dione would have just one), with allylic coupling between one of the protons on the double bond and the CH$_2$ group in the ring. The carbonyl group has the shift (185 ppm) of an acid derivative (not that of a ketone, which would be about 200 ppm) and all four carbons are different.
Ozonolysis of ketene dimer gives a very unstable compound that can be observed only at low temperatures (–78 °C or below). It has two carbonyl bands in the IR and reacts with amines to give amides, so it looks like an anhydride (Chapter 10). Can it be the previously unknown cyclic anhydride of malonic acid?

The two carbonyl bands are of high frequency, as would be expected for a four-membered ring—using the table on p. 413 we estimate 1715 + 50 cm⁻¹ (for the anhydride) + 65 cm⁻¹ (for the four-membered ring) = 1830 cm⁻¹. Both the proton and the carbon NMR are very simple: just a 2H singlet at 4.12 ppm, shifted downfield by two carbonyls, a C=O group at 160 ppm, right for an acid derivative, and a saturated carbon shifted downfield but not as much as a CH₂O group.

All this is reasonably convincing, and is confirmed by allowing the anhydride to warm to –30 °C, at which temperature it loses CO₂ (detected by the ¹³C peak at 124.5 ppm) and gives another unstable compound with the strange IR frequency of 2140 cm⁻¹. Could this be monomeric ketene? It’s certainly not either of the possible ketene dimers as we know what their spectra are like, and this is quite different: just a 2H singlet at 2.24 ppm and ¹³C peaks at 194.0 and, remarkably, 2.5 ppm. It is indeed monomeric ketene.

Squares and cubes: molecules with unusual structures

Some structures are interesting because we believe they can tell us something fundamental about the nature of bonding while others are a challenge because many people argue that they cannot be made. What do you think are the prospects of making cyclobutadiene, a conjugated four-membered ring, or the hydrocarbons tetrahedrane and cubane, which have, respectively, the shapes of the perfectly symmetrical Euclidean solids, the tetrahedron and the cube?

With four electrons, cyclobutadiene is anti-aromatic—it has 4n instead of 4n + 2 electrons. You saw in Chapter 7 that cyclic conjugated systems with 4n electrons (cyclooctatetraene, for example) avoid being conjugated by puckering into a tub shape. Cyclobutadiene cannot do this: it must be more or less planar, and so we expect it to be very unstable. Tetrahedrane has four fused three-membered rings. Although the molecule is tetrahedral in shape, each carbon atom is nowhere near a tetrahedron, with three bond angles of 60°. Cubane has six fused four-membered rings and is again highly strained.

In fact, cubane has been made, cyclobutadiene has a fleeting existence but can be isolated as an iron complex, and a few substituted versions of tetrahedrane have been made. The most convincing evidence that you have made any of these three compounds would be the extreme simplicity of the spectra. Each has only one kind of hydrogen and only one kind of carbon. They all belong to the family (CH)ₙ.

Cubane has a molecular ion in the mass spectrum at 104, correct for C₈H₈, only CH stretches in the IR at 3000 cm⁻¹, a singlet in the proton NMR at 4.0 ppm, and a single line in the carbon
NMR at 47.3 ppm. It is a very symmetrical molecule and a stable one in spite of all those four-
membered rings.

Stable compounds with a cyclobutadiene and a tetrahedrane core can be made if each hydrogen
atom is replaced by a t-buty group. The very large groups round the edge of the molecule
repel each other and hold the inner core tightly together. Now another difficulty arises—it is
rather hard to tell the compounds apart. They both have four identical carbon atoms in the
core and four identical t-butyl groups round the edge. The starting material for a successful
synthesis of both was the tricyclic ketone below identified by its strained C=O stretch and
partly symmetrical NMR spectra. When this ketone was irradiated with UV light (indicated by
‘hv’ in the scheme), carbon monoxide was evolved and a highly symmetrical compound
(t-BuC)₄ was formed. But which compound was it?

The story is made more complicated (but in the end easier!) by the discovery that this com-
 pound on heating turned into another very similar compound. There are only two possible
structures for (t-BuC)₄, so clearly one compound must be the tetrahedrane and one the cyclo-
butadiene. The problem simplifies with this discovery because it is easier to distinguish two
 possibilities when you can make comparisons between two sets of spectra. Here both com-
 pounds gave a molecular ion in the mass spectrum, neither had any interesting absorptions in
the IR, and the proton NMRs could belong to either compound as they simply showed four
identical t-Bu groups. So did the carbon NMR, of course, but it showed the core too. The first
 product had only saturated carbon atoms, while the second had a signal at 152.7 ppm for the
unsaturated carbons. The tetrahedrane is formed from the tricyclic ketone on irradiation but it
isomerizes to the cyclobutadiene on heating.

Identifying compounds from nature

The next molecules we need to know how to identify are those discovered from nature—
natural products. These often have biological activity and many useful medicines have been
discovered this way. We shall look at a few examples from different fields. The first is the sex
pheromone of the Trinidad butterfly Lycorea ceres ceres. The male butterflies start courtship by
emitting a tiny quantity of a volatile compound. Identification of this type of compound is
very difficult because of the minute amounts available but this compound was crystallized
and gave enough for a mass spectrum and an IR. The highest peak in the mass spectrum was
at 135. This is an odd number so we might have one nitrogen atom and a possible composition
of C₈H₁₀ON. The IR showed a carbonyl peak at 1680 cm⁻¹. With only this meagre information,
the first proposals were for a pyridine aldehyde.

Eventually a little more compound (6 mg!) was available and a proton NMR spectrum was
run. This showed at once that this structure was wrong. There was no aldehyde proton and
only one methyl group. More positive information was the pair of triplets showing a −CH₂CH₂−
unit between two electron-withdrawing groups (N and C=O?) and the pair of doublets for
neighbouring protons on an aromatic ring, although the chemical shift and the coupling
constant are both rather small for a benzene ring.

If we look at what we have got so far, we see that we have accounted for four carbon atoms
in the methyl and carbonyl groups and the −CH₃CH₂− unit. This leaves only four carbon
atoms for the aromatic ring. We must use nitrogen too as the only possibility is a pyrrole
ring. Our fragments are now those shown below (the black dotted lines show joins to
another fragment). These account for all the atoms in the molecule and suggest structures
such as these.
Now we need to use the known chemical shifts and coupling constants for these sorts of molecules. An N–Me group would normally have a larger chemical shift than 2.2 ppm so we prefer the methyl group on a carbon atom of the pyrrole ring. Typical shifts and coupling constants around pyrroles are shown below. Chemists do not, of course, remember these numbers; we look them up in tables. Our data, with chemical shifts of 6.09 and 6.69 ppm and a coupling constant of 2.5 Hz, clearly favour hydrogen atoms in the 2 and 3 positions, and suggest this structure for the sex pheromone, which was confirmed by synthesis and is now accepted as correct.

### Tables

The final section of this chapter contains some tables of NMR data, which we hope you will find useful in solving problems. In Chapter 13 there were a few guides to chemical shift—summaries of patterns that you might reasonably be expected to remember. But we have left the main selections of hard numbers—that you are not expected to remember—until now.

There are a few comments to explain the tables, but you will probably want to use this section as reference rather than bedtime reading. The first four tables give detailed values for various kinds of compounds and the final table gives a simple summary. We hope that you will find this last table particularly useful.

#### Effects of electronegativity

This table shows how the electronegativity of the atom attached directly to a methyl group affects the shifts of the CH₃ protons (δₖ) and the CH₃ carbon atom (δₓ) in their NMR spectra.

Effects of functional groups

Many substituents are more complicated than just a single atom and electronegativity is only part of the story. We need to look at all the common substituents and see what shifts they cause relative to the CH skeleton of the molecule. Our zero really ought to be at about 0.9 ppm for protons and at 8.4 ppm for carbon, that is, where ethane (CH3–CH3) resonates, and not at the arbitrary zero allocated to Me4Si. In the table below we give such a list. The reason for this is that the shifts (from Me4Si) themselves are not additive but the shift differences (from 0.9 or 8.4 ppm) are.

*R=CH2OH; compound is but-2-yn-1-ol.

The effects of groups based on carbon (the methyl group is joined directly to another carbon atom) appear in entries 2 to 11. All the electron-withdrawing groups based on carbonyl and cyanide have about the same effect (1.1–1.3 ppm downfield shift from 0.9 ppm). Groups based on nitrogen (Me–N bond) show a similar progression through amine, ammonium salt, amide, and nitro compound (entries 15–18). Finally, all the oxygen-based groups (Me–O bond) show large shifts (entries 19–22).
Effects of substituents on CH$_2$ groups

It is more difficult to give a definitive list for CH$_2$ groups as they have two substituents. In the table below we set one substituent as phenyl (Ph) just because so many compounds of this kind are available, and give the actual shifts relative to PhCH$_2$CH$_3$ for protons (2.64 ppm) and PhCH$_2$CH$_3$ for carbon (28.9 ppm), again comparing the substituent with the CH skeleton.

If you compare the shifts caused on a CH$_2$ group by each functional group in the table below with the shifts caused on a CH$_3$ group by the same functional group in the table on p. 423 you will see that they are broadly the same.

* Compound is (4-chloromethylphenoxymethyl)benzene.
Shifts of a CH group

We can do the same with a CH group, and in the left-hand side of the table below we take a series of isopropyl compounds, comparing the measured shifts with those for the central proton (CHMe$_2$) or carbon (CHMe$_2$) of 2-methylpropane. We set two of the substituents as methyl groups and just vary the third. Yet again the shifts for the same substituent are broadly the same.

*There is coupling between the CH and the Me$_2$ groups in the proton NMR.

Shifts in proton NMR are easier to calculate and more informative than those in carbon NMR

This final table, on p. 426, helps to explain something we have avoided so far. Correlations of shifts caused by substituents in proton NMR really work very well. Those in $^{13}$C NMR work much less well and more complicated equations are needed. More strikingly, the proton shifts often seem to fit better with our understanding of the chemistry of the compounds. There are two main reasons for this.

First, the carbon atom is much closer to the substituent than the proton. In the compounds in the table on p. 423 the methyl carbon atom is directly bonded to the substituent, while the protons are separated from it by the carbon atom of the methyl group. If the functional group is based on a large electron-withdrawing atom like sulfur, the protons will experience a simple inductive electron withdrawal and have a proportional downfield shift. The carbon atom is close enough to the sulfur atom to be shielded as well by the lone-pair electrons in the large 3sp$^3$ orbitals. The proton shift caused by S in Me$_2$S is about the same (1.23 ppm) as that caused by a set of more or less equally strong electron-withdrawing groups like CN (1.14 ppm) or ester (1.18 ppm). The carbon shift (9.7 ppm) is less than that caused by an ester (11.2 ppm) but much more than that caused by CN, which actually shifts the carbon upfield (–6.6 ppm) relative to the effect of a methyl group.
Second, the carbon shift is strongly affected not only by what is directly joined to that atom ($\alpha$ position), but also by what comes next ($\beta$ position). The right-hand half of the table on p. 424 shows what happens to methyl shifts when substituents are placed on the next carbon atom. There is very little effect on the proton spectrum: all the values are much less than the shifts caused by the same substituent on a methyl group in the table on p. 423. Carbonyls give a downfield shift of about 1.2 ppm when directly joined to a methyl group, but only of about 0.2 ppm when one atom further away. By contrast, the shifts in the carbon spectrum are of the same order of magnitude in the two tables, and the $\beta$ shift may even be greater than the $\alpha$ shift! The CN group shifts a directly bonded methyl group upfield (~6.6 ppm) when directly bonded, but downfield (14.4 ppm) when one atom further away. This is an exaggerated example, but the point is that these carbon shifts must not be used to suggest that the CN group is electron-donating in the $\alpha$ position and electron-withdrawing in the $\beta$ position. The carbon shifts are erratic but the proton shifts give us useful information and are worth understanding as a guide to both structure determination and the chemistry of the compound.

When you use this table and are trying to interpret, say, a methyl group at 4.0 ppm then you have no problem. Only one group is attached to a methyl group so you need a single shift value—it might be a methyl ester, for example. But when you have a CH$_2$ group at 4.5 ppm and you are interpreting a downfield shift of 3.2 ppm you must beware. There are two groups attached to each CH$_2$ group and you might need a single shift of about 3 ppm (say, an ester again) or two shifts of 1.5 ppm, and so on. The shifts are additive.

- Reactions of alkenes by pericyclic reactions ch34
- Rearrangement reactions ch36

Alkenes react with bromine

Bromine (Br_{2}) is brown, and one of the classic tests for alkenes is that they turn a brown aqueous solution of bromine colourless. Alkenes decolourize bromine water: alkenes react with bromine. The product of the reaction is a dibromoalkane, and the reaction on the right shows what happens with the simplest alkene, ethylene (ethene).

In order to understand this reaction, and the other similar ones you will meet in this chapter, you need to think back to Chapter 5, where we started talking about reactivity in terms of nucleophiles and electrophiles. As soon as you see a new reaction, you should immediately think to yourself, ‘Which reagent is the nucleophile; which reagent is the electrophile?’ Evidently, neither the alkene nor bromine is charged, but Br_{2} has a low-energy empty orbital (the Br–Br \sigma^*), and is therefore an electrophile. The Br–Br bond is exceptionally weak, and bromine reacts with many nucleophiles like this.

In the reaction with ethylene, the alkene must be the nucleophile, and its HOMO is the C=C \pi bond. Other simple alkenes are similarly electron-rich and they typically act as nucleophiles and attack electrophiles.

- Simple, unconjugated alkenes are nucleophilic and react with electrophiles.
When it reacts with Br₂, the alkene’s filled π orbital (the HOMO) will interact with the bromine’s empty σ* orbital to give a product. But what will that product be? Look at the orbitals involved.

The highest electron density in the π orbital is right in the middle, between the two carbon atoms, so this is where we expect the bromine to attack. The only way the π HOMO can interact in a bonding manner with the σ* LUMO is if the Br₂ approaches end-on—and this is how the product forms. The symmetrical three-membered ring product is called a bromonium ion.

How shall we draw curly arrows for the formation of the bromonium ion? We have a choice. The simplest way is just to show the middle of the π bond attacking Br–Br, mirroring what we know happens with the orbitals.

But there is a problem with this representation: because only one pair of electrons is moving, we can’t form two new C–Br bonds. We should really then represent the C–Br bonds as partial bonds. Yet the bromonium ion is a real intermediate with two proper C–Br bonds (the box in the margin presents evidence of this). So an alternative way of drawing the arrows is to involve a lone pair on bromine.

We think the first way represents more accurately the key orbital interaction involved, and we shall use that one, but the second is acceptable too.

Of course, the final product of the reaction isn’t the bromonium ion. The second step of the reaction follows on at once: the bromonium ion is itself an electrophile, and it reacts with the bromide ion lost from the bromine in the addition step. We can now draw the correct mechanism for the whole reaction, which is termed electrophilic addition to the double bond, because bromine (Br₂) is an electrophile. Overall, the molecule of bromine adds across the double bond of the alkene.
Attack of Br on a bromonium ion is a normal S_N2 substitution—the key orbitals involved are the HOMO of the bromide and the σ* of one of the two carbon–bromine bonds in the strained three-membered ring. As with all S_N2 reactions, the nucleophile maintains maximal overlap with the σ* by approaching in line with the leaving group but from the opposite side, resulting in inversion at the carbon that is attacked. The stereochemical outcome of more complicated reactions (discussed below) is important evidence for this overall reaction mechanism. You may wonder why the bromine attacks a carbon atom in the bromonium ion rather than the positively charged bromine atom. Well, in fact, it can do this as well, but the result is just regeneration of bromine and the alkene: the first step of the reaction is reversible.

Another way of thinking about bromonium ions
You can think of the bromonium ion as a carbocation that has been stabilized by interaction with a nearby bromine atom. You have seen a similar effect with oxygen—this ‘oxonium ion’ was an intermediate, for example, in the S_N1 substitution of MOM chloride on p. 338 of Chapter 15. The bromine is one atom further away but, with bromine being lower in the periodic table and having more diffuse lone pairs, it can have a similar stabilizing effect, despite the angle strain in a three-membered ring.

The two types of stabilization are not equivalent: the cation and the bromonium ion are different molecules with different shapes, while the two representations of the oxonium ion are just that—they aren’t different molecules. This stabilization of an adjacent cationic centre by a heteroatom with at least one lone pair to form a three-membered ring intermediate is not restricted to bromine or the other halogens, but is also an important aspect of the chemistry of compounds containing oxygen, sulfur, or selenium, as you will see in Chapter 27.

Oxidation of alkenes to form epoxides
The electrophilic addition of bromine to alkenes is an oxidation. The starting alkene is equivalent in oxidation level to an alcohol, but the product has two carbons at the alcohol oxidation level—the elimination reactions of dibromides to give alkynes that you met in Chapter 17 (p. 398) should convince you of this. There are a number of other oxidants containing electrophilic oxygen atoms that react with nucleophilic alkenes to produce epoxides (oxiranes). You can view epoxides as the oxygen analogues of bromonium ions, but unlike most bromonium ions they are quite stable.

The simplest epoxide, ethylene oxide (or oxirane itself), can be produced on the tonne scale by the direct oxidation of ethene with oxygen at high temperature over a silver catalyst. These conditions are hardly suitable for general laboratory use, and the most commonly used epoxidizing agents are peroxo-carboxylic acids. These peroxo-acids (or peracids) have an extra oxygen atom between the carbonyl group and their acidic hydrogen—they are esters of hydrogen peroxide (H_2O_2). They are rather less acidic than carboxylic acids because their conjugate base is no longer stabilized by delocalization into the carbonyl group. But they are electrophilic at the oxygen shown here in green because attack there by a nucleophile displaces carboxylate, a good leaving group. The LUMO of a peroxo-carboxylic acid is the σ* orbital of the weak O–O bond.

You have met epoxides being formed by intramolecular substitution reactions, but the oxidation of alkenes is a much more important way of making them. Their alternative name derives from a systematic way of naming rings: ‘ox’ for the O atom, ‘ir’ for the three-membered ring, and ‘ane’ for full saturation. You may meet oxetane (remember the oxaphosphetane in the Wittig reaction, Chapter 11, p. 238) and, while THF is never called oxolane, dioxolane is another name for five-membered cyclic acetals.
Making peroxy-acids

Peroxy-acids are prepared from the corresponding acid anhydride and high-concentration hydrogen peroxide. In general, the stronger the parent acid, the more powerful the oxidant (because the carboxylate is a better leaving group): one of the most powerfully oxidizing peroxy-acids is peroxy-trifluoroacetic acid. Hydrogen peroxide, at very high concentrations (> 80%), is potentially explosive and difficult to transport.

\[
\text{trifluoroacetic anhydride} \xrightarrow{\text{H}_2\text{O}_2} \text{peroxy-trifluoroacetic acid} + \text{trifluoroacetic acid}
\]

The most commonly used peroxy-acid is known as \textit{m}-CPBA, or \textit{meta}-chloroperoxybenzoic acid. \textit{m}-CPBA is a safely crystalline solid. Here it is, reacting with cyclohexene, to give the epoxide in 95% yield.

\[
\text{H}\xrightarrow{\text{Cl}}\text{O} \xrightarrow{\text{O}}\text{H} + \text{HOCl}
\]

95% yield

As you would expect, the nucleophilic alkene attacks the peroxy-acid from the centre of the HOMO, its \(\pi\) orbital. First, here is the orbital involved.

\[
\text{bonding interaction}
\]

HOMO = filled \(\pi\) orbital

LUMO = empty \(\sigma^*\) orbital

And now the curly arrow mechanism. The essence of the mechanism is attack by the \(\pi\) orbital of the alkene on the weak, polarized, electrophilic O–O bond, which we can represent most simply as shown in the margin. But, in the real reaction, a proton (shown in brown in this mechanism) has transferred from the epoxide oxygen to the carboxylic acid by-product. You can represent this all in one step if you draw the arrows carefully. Start with the nucleophilic \(\pi\) bond: send the electrons on to oxygen, breaking O–O and forming a new carbonyl bond. Use those electrons to pick up the proton, and use the old O–H bond’s electrons to make the second new C–O bond. Don’t be put off by the spaghetti effect—each arrow is quite logical when you think the mechanism through. The transition state for the reaction makes the bond-forming and -breaking processes clearer.

\[
\text{transition state for epoxidation}
\]

Epoxidation is stereospecific

Because both new C–O bonds are formed on the same face of the alkene’s \(\pi\) bond, the geometry of the alkene is reflected in the stereochemistry of the epoxide. The reaction is therefore stereospecific. Here are two examples demonstrating this: \textit{cis}-alkene gives \textit{cis}-epoxide and \textit{trans}-alkene gives \textit{trans}-epoxide.
More substituted alkenes epoxidize faster

Peracids give epoxides from alkenes with any substitution pattern (except ones conjugated with electron-withdrawing groups, for which a different reagent is required: see Chapter 22), but the chart below shows how the rate varies according to the number of substituents on the double bond.

Not only are more substituted double bonds more stable (as you saw in Chapter 17), but they are more nucleophilic. We showed you in Chapter 15 that alkyl groups are electron-donating because they stabilize carbocations. This same electron-donating effect raises the energy of the HOMO of a double bond and makes it more nucleophilic. You can think of it this way: every C–C or C–H bond that can allow its σ orbital to interact with the π orbital of the alkene will raise the HOMO of the alkene slightly, as shown by the energy level diagram. The more substituents the alkene has, the more the energy is raised.

The differences in reactivity between alkenes of different substitution patterns can be exploited to produce the epoxide only of the more reactive alkene of a pair, provided the supply of oxidant is limited. In the first example below, a tetrasubstituted alkene reacts in preference to a cis disubstituted one. Even when two alkenes are equally substituted, the effect of epoxidizing one of them is to reduce the nucleophilicity of the second (the new oxygen atom is electron-withdrawing, and dienes are in general more nucleophilic than alkenes; see below). The monoepoxide of cyclopentadiene is a useful intermediate and can be prepared by direct epoxidation of the diene under buffered conditions.
Nitroperoxybenzoic acid is dangerously explosive, and it is sufficiently reactive to produce this remarkable and highly strained spiro epoxide (oxaspiropentane), which was made in order to study its reactions with nucleophiles.

\[ \text{Dimethylidoxirane and carcinogenic epoxides} \]

Certain fungi, especially the mould Aspergillus sp. (which grows on damp grain), produce a group of the most carcinogenic substances known to man, the aflatoxins. One of the toxins (which are, of course, entirely natural) is metabolized in the human body to the epoxide shown below. Some chemists in the USA decided to synthesize this epoxide to investigate its reaction with DNA, hoping to discover exactly how it causes cancer. The epoxide is far too reactive to be made using a peroxy-acid (because of the acidic by-product), and instead these chemists used a reagent called dimethylidoxirane.

Dimethylidoxirane is made by oxidizing acetone with KHSO₅, but is too reactive to be stored for more than a short period in solution. After it has transferred an oxygen atom in the epoxidation step, only innocuous acetone is left, as shown by the mechanism below.

The liver is home to a wide variety of enzymes that carry out oxidation—the aim is to make unwanted water-insoluble molecules more polar and therefore soluble by peppering them with hydroxyl groups. Unfortunately, some of the intermediates in the oxidation processes are highly reactive epoxides that damage DNA. This is the means by which aromatic hydrocarbons may cause cancer, for example. Note that it is very hard to oxidize benzene by chemical (rather than biological) methods.
Electrophilic addition to unsymmetrical alkenes is regioselective

In epoxidation reactions, and in electrophilic additions of bromine, each end of the alkene is joined to the same sort of atom (Br or O). But in the addition reactions of other electrophiles, H–Br for example, there is a choice: which carbon gets the H and which gets the Br? You will need to be able to predict, and to explain, reactions of unsymmetrical alkenes with HBr, but we should start by looking at the reaction with a symmetrical alkene—cyclohexene. This is what happens. When H–Br reacts as an electrophile, it is attacked at H, losing Br\(^-\). Unlike a bromine atom, a hydrogen atom can’t form a three-membered ring cation—it has no lone pairs to use. So electrophilic addition of a proton (which is what this is) to an alkene gives a product best represented as a carbocation. This carbocation rapidly reacts with the bromide ion just formed. Overall, H–Br adds across the alkene. This is a useful way of making simple alkyl bromides.

Here are two more syntheses of alkyl bromides, but this time we need to ask our question about which end of the alkene is attacked because the alkenes are unsymmetrical (they have different substituents at each end). First, the results.

In each case, the bromine atom ends up on the more substituted carbon, and the mechanism explains why. There are two possible outcomes for protonation of styrene by HBr, but you should immediately be able to spot which is preferred, even if you don’t know the outcome of the reaction. Protonation at one end gives a stabilized benzylic cation, with its positive charge delocalized into the benzene ring.

Protonation at the other end would give a highly unstable primary cation, and therefore does not take place.

You get the same result with isobutene (2-methylpropene): the more stable tertiary cation leads to the product; the alternative primary cation is not formed.
Markovnikov’s rule
There is a traditional guideline called Markovnikov’s rule for electrophilic additions of H–X to alkenes, which can be stated as: ‘The hydrogen ends up attached to the carbon of the double bond that had more hydrogens to start with.’ We don’t suggest you learn this rule, although you may hear it referred to. As with all ‘rules’ it is much more important to understand the reason behind it. For example, you can now predict the product of the reaction below. With all due respect, Markovnikov couldn’t.

The protonation of alkenes to give carbocations is quite general. The carbocations may trap a nucleophile, as you have just seen, or they may simply lose a proton to give back an alkene. This is just the same as saying the protonation is reversible, but it needn’t be the same proton that is lost. A more stable alkene may be formed by losing a different proton, which means that acid can catalyse the isomerization of alkenes—both between Z and E geometrical isomers and between regioisomers.

E1 and isomerization
The isomerization of alkenes in acid is probably a good part of the reason why E1 eliminations in acid generally give E alkenes. In Chapter 17 we explained how kinetic control could lead to E alkenes: interconversion of E and Z alkenes under the conditions of the reaction allows the thermodynamic product to prevail. This was also discussed in Chapter 12.

Other nucleophiles may also intercept the cation, for example alkenes can be treated with HCl to form alkyl chlorides, with HI to form alkyl iodides, and with H₂S to form thiols.
**Electrophilic addition to dienes**

Earlier in the chapter you saw the epoxidation of a diene to give a monoepoxide: only one of the double bonds reacted. This is quite a usual observation: dienes are more nucleophilic than isolated alkenes. This is easy to explain by looking at the relative energy of the HOMO of an alkene and a diene—this discussion is on p. 138 of Chapter 7. Dienes are therefore very susceptible to protonation by acid to give a cation. This is what happens when 2-methylbuta-1,3-diene (isoprene) is treated with acid. Protonation gives a stable delocalized allylic cation.

![Diagram of protonation and subsequent reactions](image)

Why protonate this double bond and not the other one? The cation you get by protonating the other double bond is also allylic, but it cannot benefit from the additional stabilization from the methyl group because the positive charge is not delocalized on to the carbon carrying the methyl.

If the acid is HBr, then nucleophilic attack by Br on the cation follows. The cation is attacked at the less hindered end to give the important compound prenyl bromide. This is very much the sort of reaction you met in Chapter 15—it is the second half of an $S_n1$ substitution reaction on an allylic compound.

![Diagram of nucleophilic attack and product formation](image)

Overall, the atoms H and Br are added to the ends of the diene system. The same appears to be the case when dienes are brominated with Br$_2$.

![Diagram of bromination reaction](image)

Changing the conditions slightly gives a different outcome. If the reaction is done at lower temperatures, the bromine just adds across one of the double bonds to give a 1,2-dibromide.

![Diagram of 1,2-dibromide formation](image)

This compound turns out to be the kinetic product of the bromination reaction. The 1,4-dibromide is formed only when the reaction is heated, and is the thermodynamic product. The mechanism is electrophilic attack on the diene to give a bromonium ion, which bromide opens to give the dibromide. We have shown the bromide attacking the more substituted end of the bromonium ion—although we can’t know this for sure (attack at either end gives the same product), you are about to see (in the next section) evidence that this is the usual course of reactions of unsymmetrical bromonium ions.
This 1,2-dibromide can still react further because it can undergo nucleophilic substitution. Bromide is a good nucleophile and a good leaving group and, with an allylic system like this, an $S_N1$ reaction can take place in which both the nucleophile and the leaving group are bromide. The intermediate is a cation, but here the carbocation is disguised as the bromonium ion because bromine's lone pair can help stabilize the positive charge. Bromide can attack where it left, returning to starting material, but it can also attack the far end of the allylic system, giving the 1,4-dibromide. The steps are all reversible at higher temperatures, so the fact that the 1,4-dibromide is formed under these conditions must mean it is more stable than the 1,2-dibromide. It is not hard to see why: it has a more substituted double bond and the two large bromine atoms are further apart.

Unsymmetrical bromonium ions open regioselectively

We ignored the issue of symmetry in the alkene when we discussed the bromination of alkenes because even unsymmetrical alkenes give the same 1,2-dibromides, whichever way the bromide attacks the bromonium ion.

But when a bromination is done in a nucleophilic solvent—water or methanol, for example—solvent molecules compete with the bromide to open the bromonium ion. As you know, alcohols are much worse nucleophiles than bromide but, because the concentration of solvent is so high (remember—the concentration of water in water is 55 M), the solvent gets there first most of the time. This is what happens when isobutene is treated with bromine in methanol. An ether is formed by attack of methanol only at the more substituted end of the bromonium ion. When a functional group can react in more than one position, the choice is known as the regioselectivity of the reaction. We will return to the concept of regioselectivity in Chapter 24.

Methanol is attacking the bromonium ion where it is most hindered, so there must be some effect at work more powerful than steric hindrance. One way of looking at this is to reconsider our assumption that bromonium ion opening is an $S_N2$ process. Here, it hardly looks $S_N2$. We have a tertiary centre, so naturally you expect $S_N1$, via the cation below. But we have already said that cations like this can be stabilized by formation of the three-membered bromonium ion and, if we let this happen, we have to attack the bromonium ion, which gets us back to where we started: an $S_N2$ mechanism!
The answer to the conundrum is that substitution reactions don’t always go by pure SN1 or pure SN2 mechanisms: sometimes the mechanism is somewhere in between. Perhaps the leaving group starts to leave, creating a partial positive charge at carbon, which is intercepted by the nucleophile. This provides a good explanation of what is going on here. The bromine begins to leave and a partial positive charge builds up at carbon. The departure of bromine can get to a more advanced state at the tertiary end than at the primary end because the substituents stabilize the build-up of positive charge. A more accurate representation of this bromonium ion is shown in the margin, with one C–Br bond longer than the other and more polarized than the other.

The nucleophile now has a choice: does it attack the more accessible, primary end of the bromonium ion, or does it attack the more charged end with the weaker C–Br bond? Here, the latter is clearly the faster reaction. The transition state has considerable positive charge on carbon and is known as a loose SN2 transition state.

The products of bromination in water are called bromohydrins. They can be treated with base, which deprotonates the alcohol. A rapid intramolecular SN2 reaction follows: bromide is expelled as a leaving group and an epoxide is formed. This can be a useful alternative synthesis of epoxides avoiding peroxy-acids.

Rates of bromination of alkenes
The pattern you saw for epoxidation with peracids (more substituted alkenes react faster) is followed by bromination reactions too. The bromonium ion is a reactive intermediate, so the rate-determining step of the brominations is attack of bromine. The scale below shows the effect on the rate of reaction with bromine in methanol of increasing the number of alkyl substituents from none (ethylene) to four. Each additional alkene substituent produces an enormous increase in rate. The degree of branching (Me versus n-Bu versus t-Bu) within the substituents has a much smaller, negative effect (probably of steric origin) as does the geometry (E versus Z) and substitution pattern (1,1-disubstituted versus 1,2-disubstituted) of the alkene.
The regioselectivity of epoxide opening can depend on the conditions

Although epoxides, like bromonium ions, contain strained three-membered rings, they require either acid catalysis or a powerful nucleophile to react well. Compare these two reactions of a 1,1,2-trisubstituted epoxide. They are nucleophilic substitutions related to those we introduced in Chapter 15 (p. 352) but in that chapter we carefully avoided discussing epoxides of the unsymmetrical variety. In this example, the regiochemistry reverses with the reaction conditions. Why?

\[
\begin{align*}
\text{reaction of epoxide with} & \quad \text{reaction of epoxide with} \\
\text{basic methoxide} & \quad \text{acidic methanol} \\
\text{attack at less substituted end} & \quad \text{attack at more substituted end}
\end{align*}
\]

We’ll start with the acid-catalysed reaction because it is more similar to the examples we have just been discussing—opening happens at the more substituted end. Protonation by acid produces a positively charged intermediate that bears a passing resemblance to the corresponding bromonium ion. The two alkyl groups make possible a build-up of charge on the carbon at the tertiary end of the protonated epoxide, and methanol attacks here, just as it does in the bromonium ion. You could think of the protonated leaving group ‘pulling’ the otherwise unreactive methanol in towards the reactive centre.

\[
\begin{align*}
\text{MeOH, } & \quad \text{MeOH, } \\
\text{H} & \quad \text{H} \\
\text{MeO}^{-} & \quad \text{MeOH, HCl} \\
\text{O} & \quad \text{MeO} \\
\text{MeOH, } & \quad \text{MeOH, HCl} \\
\text{attack at} & \quad \text{attack at more substituted end}
\end{align*}
\]

In base there can be no protonation of the epoxide and no build-up of positive charge. Without protonation, the epoxide oxygen is a poor leaving group, and leaves only if ‘pushed’ by a strong nucleophile: the reaction becomes pure SN2. Steric hindrance becomes the controlling factor and methoxide attacks only the primary end of the epoxide.

\[
\begin{align*}
\text{nucleophile approaches less hindered end} & \quad \text{nucleophile approaches less hindered end} \\
\text{S_{n}2 transition state} & \quad \text{S_{n}2 transition state}
\end{align*}
\]

This example makes the matter look deceptively clear cut. But with epoxides, regioselectivity is not as simple as this because, even with acid catalysts, S_{n}2 substitution at a primary centre is fast. For example, Br⁻ in acid attacks the epoxide below mainly at the less substituted end, and only 24% of the product is produced by the ‘cation-stabilized’ pathway. It is very difficult to override the preference of epoxides unsubstituted at one end to react at that end.

\[
\begin{align*}
\text{HBr, } & \quad \text{HBr, H₂O} \\
\text{Br} & \quad \text{Br} \\
\text{H} & \quad \text{Br} \\
\text{HO} & \quad \text{Br} \\
\text{76%} & \quad \text{24%}
\end{align*}
\]

For most substitution reactions of epoxides, then, regioselectivity is much higher if you give in to the epoxide’s desire to open at the less substituted end and enhance it with a strong nucleophile under basic conditions.
Electrophilic additions to alkenes can be stereospecific

Although they really belong in Chapter 15 with other nucleophilic substitution reactions, we included the last few examples of epoxide-opening reactions here because they have many things in common with the reactions of bromonium ions. Now we are going to make the analogy work the other way by looking at the stereochemistry of the reactions of bromonium ions, and hence at the stereoselectivity of electrophilic additions to alkenes. We shall first remind you of an epoxide reaction from Chapter 15, where you saw this.

\[
\text{Me}_2\text{NH} + \text{HO} + \text{Me}_2\text{N} \rightarrow \text{Me}_2\text{N} \quad \text{SN}_2
\]

The epoxide ring opening is stereospecific: it is an \( \text{SN}_2 \) reaction and it goes with inversion. The epoxide starts on the top face of the ring and the amino group therefore ends up on the bottom face. In other words, the two groups end up \( \text{anti} \) or \( \text{trans} \) across the ring. You now know how to make this epoxide—you would use cyclopentene and \( m \)-CPBA, and in two steps you could ‘add’ an OH group and a \( \text{Me}_2\text{N} \) group \( \text{anti} \) across the double bond.

Now we can move on to look at the stereochemistry of electrophilic addition to alkenes.

**Electrophilic addition to alkenes can produce stereoisomers**

When cyclohexene is treated with bromine in carbon tetrachloride, the racemic \( \text{anti-1,2-di-bromocyclohexane} \) is obtained exclusively.

\[
\text{H} + \text{Br}_2 \rightarrow \text{Br} + \text{Br} \quad \text{CCl}_4 \text{ solvent}
\]

The result is no surprise if we think first of the formation of the bromonium ion that is opened with inversion in an \( \text{SN}_2 \) reaction.

Bromination of alkenes is stereospecific because the geometry of the starting alkene determines which product diastereoisomer is obtained. We couldn’t demonstrate this with cyclohexene because only a \( Z \) double bond is possible in a six-membered ring. But bromination or chlorination of \( Z \) and \( E \)-2-butene in acetic acid produces a single diastereoisomer in each case, and they are different from each other. \( \text{Anti} \) addition occurs in both cases—more evidence that a bromonium ion is the intermediate.
The stereochemistry of the products is a bit clearer if we redraw them, and in the scheme below the product of each reaction is shown in two different ways. Firstly, the products have been rotated to place the carbon chain in the plane of the paper: in this conformation you can clearly see that there has been an \textit{anti} addition across the \textit{E} double bond. Secondly, the middle bond has been twisted 180° to give an (unrealistically) eclipsed conformation. We show this conformation for two reasons: now you can clearly see that there has been an \textit{anti} addition across the \textit{Z} double bond too. It also makes it quite clear that the product of the \textit{E}-butene bromination is achiral: you can see the plane of symmetry in this conformation, and this is why we haven’t placed (±) signs next to the products from the \textit{E} alkene.

Note that in all three different views of each product the same stereoisomer is represented. There is no change of configuration, only changes of conformation to help you understand what is going on. If you cannot follow any of the ‘redrawing’ steps, make a model. With practice, you will soon learn to manipulate mental models in your head, and to see what happens to substituents when bonds are rotated. Most importantly, don’t let all of this more subtle stereochemical discussion cloud the simple message:

\begin{itemize}
  \item Bromine undergoes \textit{anti} addition to alkenes.
\end{itemize}
Bromonium ions as intermediates in stereoselective synthesis

You will not be surprised to learn that the other nucleophiles (water and alcohols) you saw intercepting bromonium ions earlier in the chapter also do so stereospecifically. The following reaction can be done on a large scale and produces a single diastereoisomer of the product (racemic, of course) because water opens the bromonium ion with inversion.

\[
\text{H}_2\text{O} \rightarrow \text{H}^+ \quad \text{bromonium opens with inversion}
\]

\[
\text{N-Bromosuccinimide (NBS)}
\]

The reagent used to form the bromonium ion here is called \textit{N}-bromosuccinimide, or NBS for short. Unlike the noxious brown liquid bromine, NBS is an easily handled crystalline solid and is perfect for electrophilic addition of bromine to alkenes when the bromonium ion is not intended to be opened by Br\(^-\). It works by providing a very small concentration of Br\(_2\) in solution: a small amount of HBr is enough to get the reaction going and thereafter every addition reaction produces another molecule of HBr, which liberates more Br\(_2\) from NBS. In a sense, NBS is a source of ‘Br\(^+\)’. NBS is known to act as a source of Br\(_2\) because the results of reactions of NBS and of Br\(_2\) in low concentration are identical.

When 1-methylcyclohexene is used as the starting material, there is additionally a question of regioselectivity. The alcohol attacks the more hindered end of the bromonium ion—the end where there can be greatest stabilization of the partial positive charge in the ‘loose S\(_\text{N}2\)’ transition state (see p. 437). This reaction really does illustrate the way in which a mechanism can lie in between S\(_\text{N}1\) and S\(_\text{N}2\). Configurational inversion, indicative of an S\(_\text{N}2\) reaction, happens at a tertiary centre, where you would usually expect S\(_\text{N}1\).
Adding two hydroxyl groups: dihydroxylation

Many important compounds—the carbohydrates, for example—have two hydroxyl groups on adjacent carbon atoms. They are called 1,2-diols. A good way of making a 1,2-diol is to add two hydroxyl groups across a double bond. This can be done in two ways, each of which can give a different diastereoisomer of the product.

The first way uses chemistry you have already met. When a nucleophile opens an epoxide, it generates an alcohol. If the nucleophile is water, the product is the diol. The epoxide opening in an SN2 reaction goes with stereochemical inversion, so in this example the two hydroxyl groups end up on opposite sides of the six-membered ring: the product is an anti diol. The epoxide opening reaction can be done in acid or in base.

To get the syn diol, a completely different method is used, involving the reagent osmium tetroxide, OsO4. OsO4 reacts with alkenes to deliver two hydroxyl groups—one to each end of the double bond—in a single step. Because both groups are delivered at the same time, they are always syn to one another: OsO4 carries out a syn dihydroxylation of the double bond.

The mechanism of the reaction is different from ones you have met before and goes like this: the Os starts as tetrahedral osmium(VIII) and ends up as osmium(VI). The immediate product of the reaction is an osmate ester, but these reactions are carried out in the presence of water, and hydrolysis always follows on fast, giving the diol.

Because Os(VI) is produced in the reaction, and a simple oxidation will restore it to Os(VIII), the most effective version of this reaction makes use of just a catalytic amount of Os(VIII) and a stoichiometric amount of a reoxidant, often the compound NMO, or N-methylmorpholine-N-oxide. In the example below there is only one new chiral centre, so no possibility of diastereoisomers.

Because OsO4 adds two hydroxyl groups to an alkene in a syn fashion, the overall product depends on the geometry of the alkene starting material: it is stereospecific. It is similar to bromination (p. 439) in that respect, although of course bromination is an anti addition. You can see how two different diastereoisomers are produced from different alkenes in these two examples: both dihydroxylations are mechanistically syn, but redrawing the product from the Z alkene in its more extended form reveals anti stereochemistry.
Breaking a double bond completely: periodate cleavage and ozonolysis

Sometimes it can be necessary to cleave a double bond completely, in other words to oxidize not just its $\pi$ bond (as you have seen with Br$_2$ and OsO$_4$) but its $\sigma$ bond too, as shown in the margin. This can be done in two steps using OsO$_4$ in conjunction with the reagent sodium periodate, NaIO$_4$. The diol product forms a periodate ester, which decomposes to give two molecules of aldehyde by a cyclic mechanism similar to that for the OsO$_4$ step. The NaIO$_4$ also reoxidizes the Os(VI) to Os(VIII) so only a catalytic amount of Os is required.

The process proceeds by two successive oxidations—first of the $\pi$, and then the $\sigma$ bond—with different reagents (which can be added in one step or in two—you can use NaIO$_4$ to cleave any diol, whether or not you made it using OsO$_4$). But there is another reagent that will achieve double oxidation in one step: ozone.

Ozone is a symmetrical bent molecule with a central positively charged oxygen atom and two terminal oxygen atoms that share a negative charge. Ozone is unstable, and is generated immediately before use from oxygen (using a device called an ‘ozonizer’) and bubbled into the reaction mixture. Like OsO$_4$, it adds to alkenes by a cyclic mechanism: the product is a five-membered ring with three oxygen atoms. It is extremely unstable and collapses by breaking a weak O–O bond and a C–C $\sigma$ bond, but gains two strong C=O bonds in the process.

The immediate products are a simple aldehyde on the left and a new, rather unstable looking molecule known as a carbonyl oxide on the right. But treatment of this mixture with a very mild reducing agent such as dimethyl sulfide, Me$_2$S, or triphenylphosphine, Ph$_3$P, removes the ‘spare’ oxygen and reveals the two aldehydes.

This cleavage of an alkene by ozone is an important reaction and is known as ozonolysis. Ozonolysis can be used to generate not only aldehydes, but also other functional groups. Completing the reaction with oxidizing agents such as H$_2$O$_2$ will give carboxylic acids, and more powerful reducing agents such as NaBH$_4$ will give alcohols. Here are the overall transformations:

<table>
<thead>
<tr>
<th>Ozonolysis of Alkenes to...</th>
<th>1. Ozonolysis</th>
<th>2. Reducing Agent</th>
</tr>
</thead>
<tbody>
<tr>
<td>Aldehydes</td>
<td>Me$_2$S</td>
<td>Alcohol</td>
</tr>
<tr>
<td>Carboxylic Acids</td>
<td>H$_2$O$_2$</td>
<td>Alcohols</td>
</tr>
<tr>
<td>Alcohols</td>
<td>NaBH$_4$</td>
<td></td>
</tr>
</tbody>
</table>
Ozonolysis of cyclohexenes is particularly useful as it gives 1,6-dicarbonyl compounds that are otherwise difficult to make. In the simplest case we get hexane-1,6-dioic acid (adipic acid), a monomer for nylon manufacture.

**Adding one hydroxyl group: how to add water across a double bond**

In Chapter 17 you saw alkenes being made from alcohols by E1 elimination—dehydration—under acid catalysis. The question we are going to answer in this section is: how can you make this elimination run backwards—in other words, how can you hydrate a double bond?

It is possible on occasion simply to use aqueous acid to do this. The reaction works only if protonation of the alkene can give a stable, tertiary cation. The cation is then trapped by the aqueous solvent.

In general, though, it is difficult to predict whether aqueous acid will hydrate the alkene or dehydrate the alcohol. The method we are about to show you is much more reliable. The key is to use a transition metal to help you out. Alkenes are soft nucleophiles (p. 357) and interact well with soft electrophiles such as transition metal cations. In the margin, for example, is the complex formed between an alkene and mercury(II) cation. The complex should remind you of a bromonium ion, and rightly so because its reactions are similar. Even relatively feeble nucleophiles such as water and alcohols, when used as the solvent, open the ‘mercurinium’ ion and give alcohols and ethers. In the next scheme, the mercury(II) is supplied as mercury(II) acetate, Hg(OAc)$_2$, which we shall represent with two covalent Hg–O bonds. Unsurprisingly, water attacks at the more substituted end of the positively charged mercurinium ion.

We’ve added OH and Hg(II) across the alkene, and the reaction is termed an ‘oxymercuration’. But a problem remains: how to get rid of the metal. The C–Hg bond is very weak and the simplest way to replace Hg with H is by using a reducing agent: NaBH$_4$ works fine.

Below is an example of oxymercuration–demercuration at work. The intermediate mercury compound is not isolated.
Hydration of alkynes

Oxymercuration works particularly well with alkynes. Here are the conditions, and the product, following the analogy of alkene hydration, should be the compound shown at the right-hand end of the scheme below.

But the product isolated from an alkyne oxymercuration is in fact a ketone. You can see why if you just allow a proton on this initial product to shift from oxygen to carbon—first protonate at C then deprotonate at O. C=O bonds are stronger than C=C bonds, and this simple reaction is very fast.

We now have a ketone, but we also still have the mercury. That is no problem when there is a carbonyl group adjacent because any weak nucleophile can remove mercury in the presence of acid, as shown below. Finally, another proton transfer (from O to C again) gives the real product of the reaction: a ketone.

This is a very useful way of making methyl ketones because terminal alkynes can be made using the methods of Chapter 9 (addition of metallated alkynes to electrophiles).

Anticancer compounds

The anthracyclinone class of anticancer compounds (which includes daunomycin and adriamycin) can be made using a mercury(II)-promoted alkyne hydration. You saw the synthesis of alkynes in this class on Chapter 9, where we discussed additions of metallated alkynes to ketones. Here is the final step in a synthesis of the anticancer compound deoxydaunomycinone: the alkyne is hydrated using Hg²⁺ in dilute sulfuric acid to give the final product.
**Hydroboration**

These methods for adding water across a double or triple bond involve cationic intermediates, and always end up putting the new hydroxyl group at the position best able to stabilize a positive charge (see p. 433). By what about addition of water the other way round? How would you do the reaction in the margin for example?

The answer is to make use of yet another element: boron. Boranes, including both BH₃ itself and analogues with one or two alkyl groups, HBR₂ (an important example is shown in the margin), add to alkenes to make a new C–H bond and a new C–B bond by a mechanism we can write like this. The alkene pushes electrons into the boron’s empty p orbital, while the hydrogen transfers onto the alkene.

![Interactive mechanism of hydroboration](image)

Importantly, if the alkene is unsymmetrical, the boron tends to end up on the less substituted carbon atom. This reaction can happen several times so, for example, if you start with an alkene and BH₃, you will typically end up with a trialkylborane:

![Interactive mechanism of hydroboration](image)

So far so good, if you want to make boranes, but we started out this section posing ourselves the problem of adding water across a double bond. This is where a quirk of boron chemistry helps us out. The C–B bond(s) we have just created can be oxidized to C–O bonds by using a mixture of NaOH and H₂O₂. The mixture generates the hydroperoxide anion HO⁻O⁻, which adds to that important empty p orbital on boron. The product is a negatively charged structure, shown below.

![Interactive mechanism of hydroboration](image)

This is not stable, and it can decompose by a mechanism you should look at closely. It is not one which is familiar to you, but it makes sense if you think about it. The O–O bond is weak and can break, losing HO⁻. As it does so, one of the alkyl groups on boron can migrate from B to O, relieving the boron atom of its negative charge, to give the structure shown below.

![Interactive mechanism of hydroboration](image)

We now have the C–O bond where we want it, and all that has to happen is for the hydroxide anion to come back in and displace B from the alcohol product. The product, on protonation, is our alcohol. How can we be sure the correct R group will migrate? Well, if we use BH₃, we will get a trialkyborane, where all three groups on boron are the same, and all three C–B bonds can be oxidized one after another. If we use the HBR₂ reagent 9-BBN, then only the non-cyclic substituent formed in the hydroboration reaction will migrate, selectively giving us the product we want.
To conclude...a synopsis of electrophilic addition reactions

Electrophilic addition to double bonds gives three-membered ring intermediates with \( \text{Br}_2 \), with \( \text{Hg}^{2+} \), and with peroxy-acids (in which case the three-membered rings are stable and are called epoxides). All three classes of three-membered rings react with nucleophiles to give 1,2-difunctionalized products with control over (1) regioselectivity and (2) stereoselectivity. Protonation of a double bond gives a cation, which also traps nucleophiles, and this reaction can be used to make alkyl halides. Some of the sorts of compounds you can make by the methods of this chapter are shown below.

Further reading

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at http://www.oxfordtextbooks.co.uk/orc/clayden2e/
We make no apologies for the number of pages we have devoted to carbonyl chemistry. The first reactions you met, in Chapter 6, involved carbonyl compounds. Then in Chapters 9, 10, and 11 we considered different aspects of nucleophilic attack on electrophilic carbonyl compounds. But carbonyl compounds have two opposed sides to their characters. They can be nucleophilic as well: electrophilic attack on aldehydes, ketones, and acid derivatives is a useful reaction too. How can the same class of compound be subject to both nucleophilic and electrophilic attack? The resolution of this paradox is the subject of this chapter, where we shall see that most carbonyl compounds exist in two forms—one electrophilic and one nucleophilic. The electrophilic form is the carbonyl compound itself and the nucleophilic form is called the enol.

Would you accept a mixture of compounds as a pure substance?

You can buy dimedone (5,5-dimethylcyclohexane-1,3-dione) from chemical suppliers. If, as is wise when you buy any compound, you run an NMR spectrum of the compound to check on its purity, you might be inclined to send the compound back. In CDCl₃ solution it is clearly a mixture of two compounds. Overleaf you can see ¹H and ¹³C NMR spectra of the mixture, with the peaks of the dione in red.
The majority of the sample is indeed 5,5-dimethylcyclohexane-1,3-dione. What is the rest? The other component has a similar spectrum and is clearly a similar compound: it has the 6H singlet for the CMe₂ group and the two CH₂ groups at the side of the ring; it also has five signals in its ¹³C NMR spectrum. But it has a broad signal at δ₇ 8.15, which looks like an OH group, and importantly a sharp signal at δ₇ 5.5 in the double-bond region. It also has two different sp² carbon atoms. All this fits the enol structure below.

Tautomerism: formation of enols by proton transfer

An enol is exactly what the name implies: an ene-ol. It has a C=O double bond and an OH group joined directly to it. In the case of dimedone, the enol must be formed by a transfer of a proton from the central CH₂ group of the keto form to one of the OH groups, a reaction known as enolization.

Notice that there is no change in pH—a proton is lost from carbon and gained on oxygen. It is a strange reaction in which little happens: the only change is the transfer of one
proton and the shift of the double bond. Interconversions like this are given the name tautomerism.

**Tautomerism**

Any reaction that simply involves the intramolecular transfer of a proton, and nothing else, is called a tautomerism. Here are two other examples.

![Tautomerism in a carboxylic acid](image1)

![Tautomerism in an imidazole](image2)

This sort of chemistry was discussed in Chapter 8, where the acidity and basicity of atoms were the prime considerations. In the first case the two tautomers are the same and so the equilibrium constant must be exactly 1 (the mixture must be exactly 50:50). In the second case (imidazole-containing compounds appear on p. 178) the equilibrium will lie on one side or the other depending on the nature of R.

---

**Why don’t simple aldehydes and ketones exist as enols?**

When we were looking at the spectra of carbonyl compounds in Chapters 13 and 18 we saw no signs of enols in IR or NMR spectra. Dimedone is exceptional (we will discuss why later) and while any carbonyl compound with protons adjacent to the carbonyl group can enolize, simpler carbonyl compounds like cyclohexanone or acetone have only a trace of enol present under ordinary conditions. The equilibrium lies well over towards the keto form (the equilibrium constant $K$ for acetone enolization is about $10^{-6}$).

This is because the combination of a C=O double bond and an O–H single bond is (slightly) less stable than the combination of a C=O double bond and a C–H single bond. The balance between the bond energies is quite fine. On the one hand, the O–H bond in the enol is a stronger bond than the C–H bond in the keto but, on the other hand, the C=O bond of the ketone is much stronger than the C=C bond of the enol. Some average values for these bonds are shown on the right.

Typical amounts of enols in solution are about one part in $10^5$ for normal ketones. So why do we think they are important? Because enolization is just a proton transfer, it is occurring all the time even though we cannot detect the minute proportion of the enol. Let’s look at the evidence for this statement.

---

**Evidence for the equilibration of carbonyl compounds with enols**

If you dissolve a simple carbonyl compound (for example, 1-phenylpropan-1-one, ‘propiopheneone’) in D$_2$O and run a series of $^1$H NMR spectra over a period of time, the signal for protons next to the carbonyl group very slowly disappears. If the compound is isolated from the solution afterwards, the mass spectrum shows that those hydrogen atoms have been replaced by deuterium atoms: there is a peak at $(M + 1)^+$ or $(M + 2)^+$ instead of at $M^+$.

Enolization usually means losing a proton from C and gaining one at O. But in D$_2$O all of the ‘protons’ are in fact ‘deuterons’ (D$^+$, or 2H$^+$), so initially an enol with an ‘OD’ group forms. This doesn’t matter, though, because when the enol form reverts to the keto form, it loses the D from O. But what does matter is that it also picks up a deuteron instead of a proton at C.

![1-phenyl-1-propanone](image3)

Notice that the double bond in this enol could be either E or Z. It is drawn as Z here, but in reality is probably a mixture of both, although this is irrelevant to the reaction. We shall not be concerned with the geometry of enols in this chapter, but there are some reactions that you will meet in later chapters where it is important, and you need to appreciate that the possibility exists.
The process can now be repeated: either the D or the H could be lost this time, but eventually it is certain that the huge excess of D over H in the solvent will mean that both H atoms adjacent to the carbonyl group are replaced by D.

We can detect this exchange by the slow disappearance of the 2H signal for the protons on the carbon next to the carbonyl group. There are, of course, eight other hydrogen atoms in the molecule but they are not affected by enolization.

**Enolization is catalysed by acids and bases**

Enolization is, in fact, quite a slow process in neutral solution, even in D<sub>2</sub>O (the exchange described above might take place over a period of hours to days at room temperature), and we would catalyse it with acid or base if we really wanted it to happen fast. In the acid-catalysed reaction, the molecule is first protonated on oxygen and then loses a proton from C in a second step. We shall use a different example here to show that aldehydes form enols too, but acid or base will catalyse enolization of any carbonyl compound in the same way.

**Acid-catalysed enolization of an aldehyde**

This is a more detailed mechanism for enolization than those we have been drawing because it shows that something (here a water molecule) must actually be removing the proton from carbon. Although this reaction will occur faster than the uncatalysed enolization, the equilibrium is not changed and we still cannot detect the enol spectroscopically.

In the base-catalysed reaction the C–H proton is removed first by the base, say a hydroxide ion, and the proton added to the oxygen atom in a second step.

**Base-catalysed enolization of an aldehyde**

This is a good mechanism too because it shows that something must remove the proton from carbon and something (here a water molecule—we don’t, of course, have protons available in basic solution) must put the proton on the oxygen atom.

Notice that both of these reactions are genuinely catalytic. You get the proton back again (in the form of H<sub>3</sub>O<sup>+</sup>) at the end of the acid-catalysed mechanism, and you get the hydroxide ion back again at the end of the base-catalysed mechanism.

**The intermediate in the base-catalysed reaction is an enolate ion**

There are some more insights to be gained from the base-catalysed reaction. The intermediate anion is called the **enolate ion**. It is the conjugate base of the enol and can be formed either
directly from the carbonyl compound by the loss of a C–H proton or from the enol by loss of the O–H proton.

The enolate ion is one of those three-atom four-electron systems related to the allyl anion that you met in Chapter 7. The negative charge is mainly on oxygen, the most electronegative atom. We can show this with curly arrows using the simplest enolate possible (from \(\text{MeCHO}\)).

The enolate is a delocalized system, with negative charge carried on both C and O—we use a double-headed conjugation arrow to connect these two representations because the oxyanion and carbanion structures are just two different ways to represent the same thing. We shall usually prefer the oxyanion structure as it is more realistic.

You can say the same thing in orbitals.

On the left you see the populated orbitals of the allyl anion and on the right the corresponding orbitals of the enolate ion. The allyl anion is, of course, symmetrical. Two changes happen when we replace one carbon by an oxygen atom. Because oxygen is more electronegative, both orbitals go down in energy. The orbitals are also distorted. The lower-energy atomic orbital of the more electronegative oxygen contributes more to the lower-energy orbital (\(\psi_1\)) and correspondingly less to \(\psi_2\). The charge distribution comes from both populated orbitals so the negative charge is spread over all three atoms, but is mostly on the ends. The important reactive orbital is the HOMO (\(\psi_2\)), which has the larger orbital on the terminal carbon atom.

In the enolate, the oxygen atom has more of the negative charge, but the carbon atom has more of the HOMO. One important consequence is that we can expect reactions dominated by charges and electrostatic interactions to occur on oxygen and reactions dominated by orbital interactions to occur on carbon. Thus acyl chlorides tend to react at oxygen to give enol esters.

It’s important to recognize the difference between this conjugation and the tautomerism that interconverts the keto and enol forms of a carbonyl compound, which is a real equilibrium between two different structures and must be represented by equilibrium arrows.

In other words, the oxygen is a hard nucleophilic centre and the carbon is a soft nucleophilic centre. See Chapter 15, p. 357.
acetone base enolate anion reacts through oxygen with acyl chloride

enolate anion reacts through carbon with alkyl halide

acetone base enolate anion reacts through oxygen with acyl chloride

acetone base enolate anion reacts through carbon with alkyl halide

 acetone

while alkyl halides tend to react at carbon.

We shall be looking at these reactions in detail in Chapter 25. For the rest of this chapter we will turn to some simpler consequences of enolization and some reactions of enolates with simple heteroatom-based electrophiles.

**Summary of types of enol and enolate**

Time to recap and summarize the various kinds of enol and enolate that can form from carbonyl compounds. You have already seen that ketones and aldehydes enolize. With an unsymmetrical ketone, more than one enol or enolate ion is possible.

Enolizable ketones

- cyclohexanone
- 2-butanone
- 2,2-dimethylpropanal (pivaldehyde)

Enolizable aldehydes

- benzaldehyde
- benzophenone
- 2,2-dimethylpropanal (pivaldehyde)
- formaldehyde

Non-enolizable carbonyl compounds

- formaldehyde
- benzaldehyde
- benzophenone

All carboxylic acid derivatives can form enols of some kind. Those of esters are particularly important and either enols or enolates are easily made. It is obviously necessary to avoid water in the presence of acid or base, as esters hydrolyse under these conditions. One solution is to use the alkoxide belonging to the ester (MeO⁻ with a methyl ester, EtO⁻ with an ethyl ester, and so on) to make enolate ions.

\[
\text{MeO}^- + \text{H}_2\text{C}==\text{O} \rightarrow \text{MeO}^- \cdot \text{H} + \text{H}_2\text{C}==\text{O}^- \cdot \text{Me}\]

Then, if the alkoxide does act as a nucleophile, there’s no harm done as the same ester is simply regenerated.
The carbonyl group is accepting electrons in both the enolization step and the nucleophilic attack. The same compounds that are the most electrophilic are also the most easily enolizable. This makes acyl chlorides very enolizable. To avoid nucleophilic attack, we cannot use chloride ion as base since chloride is not basic, so we must use a non-nucleophilic base such as a tertiary amine. The resulting enolate is not stable as it can eliminate chloride ion, a good leaving group, to form a ketene. This works particularly well in making dichloroketene from dichloroacetyl chloride as the proton to be removed is very acidic.

Carboxylic acids do not form enolate anions easily as the base first removes the acidic OH proton. This also protects acids from attack by most nucleophiles.

In acid solution, there are no such problems and ‘ene-diols’ are formed.

Amides (unless they are tertiary) also have rather acidic protons, though not, of course, as acidic as those of carboxylic acids. Attempted enolate ion formation in base removes an N–H proton rather than a C–H proton. Amides are also the least reactive and the least enolizable of all acid derivatives, and their enols and enolates are rarely used in reactions.

It is not even necessary to have a carbonyl group to observe very similar reactions. Imines and enamines are related by the same kind of tautomeric equilibria.
With a primary amine (here PhNH₂) a reasonably stable imine is formed, but with a secondary amine (here a simple cyclic amine) the imine itself cannot be formed and the iminium salt is less stable than the enamine.

Just as enamines are the nitrogen analogues of enols, aza-enolates are the nitrogen analogues of enolates. They are made by deprotonating enamines with strong base. Nitroalkanes are much more acidic and form enolate-like anions in quite weak base.

\[
\text{Formation of aza-enolate} \quad \text{Formation of nitromethane anion}
\]

Nitriles (cyanides) also form anions and require strong base as the negative charge is delocalized onto only a single nitrogen atom. The anion is a linear system like ketene, allene, or carbon dioxide.

\[
\text{Formation of nitromethane anion}
\]

**Requirement for enolization**

Any organic compound with an electron-withdrawing functional group, with at least one π bond joined to a saturated carbon atom having at least one hydrogen atom, may form an enol in neutral or acid solution. Many also form enolates in basic solution (exceptions being carboxylic acids, and primary and secondary amides).

The enols will probably not be detectable in solution (only about one part in 10⁴–10⁶ is enol for most compounds). Some compounds by contrast form stable enols, and we’ll look at these next, before coming back to how enols and enolates react.

**Stable enols**

We have established that the enol is, in general, less stable than the keto form of the molecule. We might hope to see stable enols if we changed that situation by adding some feature to the molecule that stabilized the enol thermodynamically. Or we might try to create an enol that would revert only slowly to the keto form—in other words, it would be kinetically stable. We shall look at this type first.

**Kinetically stable enols**

The formation of enols is catalysed by acids and bases. The reverse of this reaction—the formation of ketone from enol—must therefore also be catalysed by the same acids and bases. If you prepare simple enols in the strict absence of acid or base they have a reasonably long lifetime. A famous example is the preparation of the simplest enol, vinyl alcohol, by heating ethane-1,2-diol (glycol—antifreeze) to very high temperatures (900 °C) at low pressure. Water is lost and the enol of acetaldehyde is formed. It survives long enough for its proton NMR spectrum to be run, but gives acetaldehyde slowly.
The spectrum illustrates the electronic effect of the oxygen atom on the double bond. The alkene proton next to OH (in green) is deshielded and the two alkene protons on the other carbon atom (in orange) are shielded as you would expect from the feeding of electrons into the double bond by the OH group. The coupling constants across the double bond are as expected too: a large trans coupling (14.0 Hz) and a smaller cis coupling (6.5 Hz). The very small geminal coupling is typical of a terminal double bond CH₂ group.

Other enols can be made that are stable because it is very difficult for the carbon atom to be protonated. In the example on the right, the two substituted benzene rings crowd the enol and prevent approach of a protonating agent. The rings twist out of the plane of the double bond and shield both faces of the enol from attack by a proton.

**Thermodynamically stable enols: 1,3-dicarbonyl compounds**

We started this chapter by looking at a molecule that contained about 33% enol in solution—dimedone (shown on the right). In fact, this is just one example of the class of 1,3-dicarbonyl compounds (also called \(\beta\)-dicarbonyls), many of which contain substantial amounts of enol and may even be completely enolized in polar solvents.

We need now to examine why these enols are so stable. The main reason is that this unique (1,3) arrangement of the two carbonyl groups leads to enols that are conjugated—rather like a carboxylic acid.

Look back at the NMR spectrum of dimedone (p. 450) and you’ll see that the two CH₂ groups within the ring seem to be the same, although they are different (a and b)—even the delocalization we have just proposed does not make them equivalent. This must mean that the enol is in rapid equilibrium with another identical enol. This is not delocalization—a proton is moving—so it is **tautomerism**.
Once again, this is very like the situation in a carboxylic acid. The two enols equilibrate (tautomerize) so fast in CDCl₃ solution that the NMR spectrometer records an ‘averaged’ spectrum. By contrast, equilibration between the enol and keto forms is sufficiently slow that the NMR spectrometer records separate signals for the keto and enol forms.

Other 1,3-dicarbonyl compounds also exist largely in the enol form. In some examples there is an additional stabilizing factor, intramolecular hydrogen bonding. Acetylacetone (propane-2,4-dione) has a symmetrical enol stabilized by conjugation. The enol form is also stabilized by a very favourable intramolecular hydrogen bond in a six-membered ring.

\[
\begin{align*}
\text{enol form of acetylacetone stabilized by an intramolecular hydrogen bond} \\
\text{enol form of acetylacetone stabilized by conjugation}
\end{align*}
\]

The hydrogen-bonded enol structure looks unsymmetrical, but in fact, as with dimedone, the two identical enol structures interconvert rapidly by proton transfer, that is, by tautomerism.

The 1,3-dicarbonyl compound need not be symmetrical, and if it is not then two different enol forms will interconvert by proton transfer. Below is a cyclic keto-aldehyde that exists entirely as a pair of rapidly equilibrating enols. The proportions of the three species can be measured by NMR: there is <1% keto-aldehyde, 76% of the first enol, and 24% of the second.

\[
\begin{align*}
\text{two different stable enols rapidly interconverting by tautomerism}
\end{align*}
\]

More examples of stable enols

Pfizer’s anti-inflammatory drug ‘Feldene’ (used to treat arthritis) is a stable enol based on a 1,3-dicarbonyl compound. It also contains amide and sulfonamide groups but you should be able to pick out the enol part.

\[
\begin{align*}
Piroxicam (\text{Feldene}^{\text{®}}) & \quad \text{once-a-day treatment for arthritis} \\
\text{Leptospermone (\text{Callisto}^{\text{®}})} & \quad \text{herbicide produced by the bottle-brush plant}
\end{align*}
\]

Stable enols occur in nature too. Leptospermone is a herbicide produced by \textit{Callistemon citrinus}, the bottle-brush plant, to keep down competitors, and it has been used commercially as ‘Callisto’ to protect maize. It is a tetraketone, but exists entirely as a mixture of tautomeric enols. Note that the carbonyl group in orange is unable to form an enol: it has no \(\alpha\) hydrogens.

Vitamin C has a five-membered ring containing two carbonyl groups but normally exists as a very conjugated ene-diol.
We can show the delocalization and explain why vitamin C is called ascorbic acid at the same time. The green enol proton is acidic because the anion is delocalized over the 1,3-dicarbonyl system.

The ultimate in stable enols has to be the Ph-enol. Aromatic alcohols, or phenols, which prefer the substantial advantage of aromaticity to the slight advantage of a C=O over a C=C double bond. They exist entirely in the phenol form. Like ascorbic acid, phenol is also quite acidic (pKₐ 10)—it used to be called carbolic acid.

Consequences of enolization

Unsaturated carbonyl compounds prefer to be conjugated

It is difficult to keep a β,γ-unsaturated carbonyl compound because the double bond tends to move into conjugation with the carbonyl group in the presence of traces of acid or base. The intermediate is, of course, an enol in acid solution but an enolate ion in base.

Protonation at the α position takes the molecule back to the unconjugated ketone, but protonation in the γ position gives the more stable conjugated isomer. All the reactions are equilibria so the conjugated isomer ends up predominating.

Racemization

Any stereogenic centre next to a carbonyl group is precarious because enolization will destroy it. It would be foolish to try and make optically active β-keto esters whose only stereogenic centre was between the two carbonyl groups. Although the keto-ester is chiral, the enol is flat and cannot be chiral. The two forms are in rapid equilibrium so all optical activity would quickly be lost.
Compounds with one carbonyl group next to the stereogenic centre can be made but care still needs to be taken. The α amino acids, the component parts of proteins, are like this. They are perfectly stable and do not racemize in aqueous acid or base. In base they exist as carboxylate anions that do not enolize, as explained above. Enolization in acid is prevented by the –NH₃⁺ group, which inhibits the protonation of the carbonyl group necessary for enol formation.

Amino acids can be converted into their N-acetyl derivatives with acetic anhydride. These N-acetyl amides can be racemized on recrystallization from hot acetic acid, no doubt by enolization. The amino group is no longer basic, and is not protonated in acid, so protonation on the carbonyl group and hence enolization is now possible.

You may think it a crazy idea to want to racemize an amino acid. Supposing, however, that you are preparing a pure (S)-amino acid from a racemate by resolution. Half your material ends up as the wrong (R)-enantiomer and you don’t want just to throw it away. If you racemize it you can put it back into the next resolution and convert half of it into the (S)-acid. Then you can racemize what remains and so on.

Racemization in vivo

Some compounds may be racemized inside the human body. Bacterial cell walls are built partly from ‘unnatural’ (R)-amino-acids, which humans can’t digest. But we can use enzymes to racemize them.

There is an important group of analgesic (pain-killing) drugs, such as ibuprofen, based on the aryl-propionic acid structure. Ibuprofen can be bought over the counter in chemists’ shops as Nurofen. Only the (S)-enantiomer of ibuprofen is an effective painkiller but the compound is administered as the racemate. The body does the rest, racemizing the compound by enolizing it.

Reaction with enols or enolates as intermediates

We have already seen that exchange of hydrogen for deuterium, movement of double bonds into conjugation, and racemization can occur with enols or enolates as intermediates. These are chemical reactions of a sort, but it is time to look at some reactions that make significant changes to the carbonyl compound.
Halogenation

Carbonyl compounds can be halogenated in the α position by halogens (such as bromine, Br₂) in acidic or basic solutions. We shall look at the acid-catalysed reaction first because it is simpler. Ketones can usually be cleanly brominated using acetic acid as solvent.

\[
\text{acetone} + \text{Br}_2 + \text{HOAc} \rightarrow \text{bromoacetone}
\]

The first step is acid-catalysed enolization and the electrophilic bromine molecule then attacks the nucleophilic carbon of the enol. The arrows show why this particular carbon is the one attacked.

Notice that the acid catalyst is regenerated at the end of the reaction. The reaction need not be carried out in an acidic solvent, or even with a protic acid at all. Lewis acids make excellent catalysts for the bromination of ketones. This example with an unsymmetrical ketone gives 100% yield of the bromoketone with catalytic AlCl₃ in ether as solvent.

Bromination occurs nowhere else in the molecule—not on the benzene ring (which, as you will see in the next chapter, it easily might under these conditions), nor on any other atom of the aliphatic side chain. This is because only one position can form an enol and the enol is more reactive towards bromine than the aromatic ring.

These mechanisms should remind you of alkene bromination (p. 427)—except that here the attack on the bromine is assisted by an electron pair on oxygen. Enols are more nucleophilic than simple alkenes—the HOMO is raised by the interaction with the oxygen's lone pairs and looks not unlike the HOMO of the enolate anion we discussed on p. 453. The product, instead of being a bromonium ion (which would undergo further reactions), loses a proton (or the Lewis acid) to give a ketone.

Bromination of acid derivatives is usually carried out not on the acid itself but by converting it to an acyl bromide or chloride, which is not isolated but gives the α-bromoacyl halide via the enol. This used to be done in one step with red phosphorus and bromine, but a two-step
process is usually preferred now, and the bromoester is usually made directly without isolating any of the intermediates. We can summarize the overall process like this.

\[
\begin{align*}
\text{OH} & \xrightarrow{SOCl_2} \text{Cl} & \text{Br} & \xrightarrow{MeOH} \text{BrO} & \text{OMe} \\
\end{align*}
\]

The formation of the acyl chloride with \(\text{SOCl}_2\) and the conversion of the \(\alpha\)-bromoacyl chloride into the bromoester with \(\text{MeOH}\) are simple nucleophilic substitutions at the carbonyl group, as described in Chapter 10. The intermediate stage, the bromination of the very easily enolized acyl chloride, is a typical enol bromination.

\[
\begin{align*}
\text{Cl} & \xrightarrow{\text{Br}_2} \text{OH} & \xrightarrow{\text{Br}_2} \text{Cl} & \xrightarrow{\text{Br}_2} \text{Cl} & + \text{HBr} \\
\end{align*}
\]

**Base-promoted halogenation**

In base, bromination is different and more complicated because it usually won’t stop with the introduction of one halogen atom. We’ll use the bromination of acetone as our example: the first step will now be a base-catalysed enolization to give the enolate ion instead of the enol. The enolate ion can attack a bromine molecule in a very similar way to the attack of the enol on bromine. The enolate will, of course, be even more reactive than the enol (the enolate carries a negative charge).

\[
\begin{align*}
\text{H} & \xrightarrow{\text{BrOH}} \text{OH} & \xrightarrow{\text{BrOH}} \text{Br} & \xrightarrow{\text{Br}_2} \text{Br} & + \text{Br}^\text{\text{\text{o}}} \\
\end{align*}
\]

The problem is that the reaction does not stop at this point. The first step was the removal of a proton and the protons between the carbonyl group and the bromine atom in the product are more acidic than those in the original acetone because of the electron-withdrawing bromine atom. Bromoacetone forms an enolate faster than acetone does.

\[
\begin{align*}
\text{H} & \xrightarrow{\text{BrOH}} \text{OH} & \xrightarrow{\text{BrOH}} \text{Br} & \xrightarrow{\text{Br}_2} \text{Br} & \xrightarrow{\text{Br}_2} \text{Br} & + \text{Br}^\text{\text{\text{o}}} \\
\end{align*}
\]

Dibromoacetone is formed. Now we have one remaining proton in between the carbonyl group and two bromine atoms. It is even more acidic and so forms a new enolate ion even more quickly. The first product observable in any amount is tribromoacetone.

\[
\begin{align*}
\text{H} & \xrightarrow{\text{BrOH}} \text{OH} & \xrightarrow{\text{BrOH}} \text{Br} & \xrightarrow{\text{Br}_2} \text{Br} & \xrightarrow{\text{Br}_2} \text{Br} & \xrightarrow{\text{Br}_2} \text{Br} & + \text{Br}^\text{\text{\text{o}}} \\
\end{align*}
\]

But even this is not the end of the story. To see why, we need to backtrack a bit. You may already have asked yourself, ‘Why doesn’t the hydroxide ion, being a nucleophile, attack the carbonyl group?’ This is a general question you might ask about all enolizations in base. The answer is that it does. The reaction is shown in the margin. A tetrahedral intermediate forms.

What can happen now? This tetrahedral intermediate will revert to a carbonyl compound by expelling the best leaving group. \(\text{Me}^-\) can never act as a leaving group: the only possible leaving group is the hydroxide ion (\(\text{pK}_a\) of water = 15.7), so it just drops out again.

This state of affairs continues until we reach the tribromoketone. The \(\text{CBr}_3^-\) group now has a chance to be a leaving group since the carbanion is stabilized by three bromine atoms. A real reaction occurs:
These initial products exchange a proton to reveal the true products of the reaction—the anion of a carboxylic acid and tribromomethane (CHBr₃).

The same thing happens with iodine, and we can summarize the whole process with iodine using a general structure for a carbonyl compound bearing a methyl group. It must be a methyl group because three halogens are necessary to make the carbanion into a leaving group. This reaction is often called the ‘iodoform’ reaction. Iodoform was an old name for triiodomethane, just as chloroform is still used for trichloromethane. It is one of the rare cases where nucleophilic substitution at a carbonyl group results in the cleavage of a C–C single bond.

Acid conditions are best for halogenation

Halogenation of carbonyl compounds should be carried out in acid solution. Attempts in basic solution lead to multiple substitutions and C–C bond cleavage.

Why does acid-catalysed halogenation work better?

The reason why halogenation in base continues until all the hydrogens have been replaced is clear: each successive halide makes the remaining proton(s) more acidic and the next enolization easier. But why does acid-catalysed halogenation stop after the introduction of one halogen? It would be more accurate to say that it can be made to stop after one halogen is introduced if only one equivalent of halogen is used. Acid-catalysed halogenation will continue if there is more halogen available.

However, the second halogen goes on the other side of the carbonyl group, if it can. It is evidently the case that the second halogenation is slower than the first. Most of the intermediates are positively charged and hence destabilized by the presence of a halogen. The bromoketone is less basic than acetone so less of the reactive protonated form is present. This slows down any further electrophilic attack.

The second step is the rate-determining step, and the presence of a bromine atom at the α position slows this step down still further: if a proton can be lost from a different α position—one without a Br atom—it will be. The transition state for proton removal illustrates why bromine slows this step down. The part of the structure close to the bromine atom is positively charged.
We can add a useful piece of evidence to this weak-sounding explanation. The halogenation of an unsymmetrical dialkyl ketone gives different results in acid and in base. In base halogenation occurs preferentially on a methyl group, that is, on the less highly substituted side. In acid solution by contrast, the first (and only) halogenation occurs on the more substituted side of the carbonyl group. Alkyl groups have the opposite effect to bromine atoms—they stabilize positive charges. So the reactions of an enol, with a positively charged transition state, are faster at more highly substituted positions. Enolates react through negatively charged transition states and are faster at less highly substituted carbon atoms.

**Nitrosation of enols**

Now for a reaction with nitrogen as an electrophile that illustrates enol reactivity and reminds us that tautomerism happens with functional groups other than the carbonyl. Let us suppose you have a carbonyl compound and wish to introduce another carbonyl group next to the first. One way you might go about it is like this:

The first step involves the formation of the weak acid nitrous acid (HNO₂ or, more helpfully, HONO) from the sodium salt and the strong acid HCl. Nitrous acid is itself protonated and then loss of water creates the reactive electrophile NO⁺.

This diatomic cation, isoelectronic with carbon monoxide, is electrophilic at nitrogen and attacks the enol of the ketone to form an unstable nitroso compound.
The nitroso compound is unstable because it can tautomerize with the transfer of a proton from carbon to the oxygen of the nitroso group. This process is exactly like enolization but with \( \text{N}=\text{O} \) in the place of the \( \text{C}=\text{O} \) group. It gives an oxime as the stable ‘enol’. The oxime’s \( \text{O}–\text{H} \) can form an intramolecular hydrogen bond with the ketone carbonyl group. Hydrolysis of the oxime reveals the second ketone.

If the ketone is unsymmetrical, this reaction will occur on the more substituted side, for the same reason that acid-catalysed enol bromination gives the more substituted \( \alpha \)-bromocarbonyl compound (see the box on p. 463).

Before we move on to any more reactions, we want you to take away this message from the reactions of enols and enolates with \( \text{Br}_2 \) and with \( \text{NO}^+ \):

- **Enols and enolates generally react with electrophiles at carbon.**

### The nitroso group

The difference between the nitro and nitroso groups is one of oxidation state and conjugation. The much more stable nitro group has a trigonal nitrogen atom with no lone pair; the \( \text{N}=\text{O} \) bond is delocalized. The nitroso group has a trigonal nitrogen atom with a lone pair in the plane; the \( \text{N}=\text{O} \) bond is not delocalized. Both can form ‘enols’ but the equilibria are biased in different directions.

### Stable equivalents of enolate ions

#### Lithium enolates

Even with fairly strong bases such as hydroxides or alkoxides, most carbonyl compounds are converted to their enolates only to a very small extent. A typical value for the \( pK_a \) of protons adjacent (\( \alpha \)) to a carbonyl group is 20–25, while the \( pK_a \) of methanol is around 16, so we can only hope for about 1 part enolate in \( 10^4 \) parts carbonyl compound. With a much stronger base this all changes, and the enolate is formed quantitatively from the carbonyl compound. This is a very important result that we shall capitalize on in Chapters 25 and 26. The base usually used is LDA (lithium diisopropylamide), and it works like this.
LDA is bulky, so it does not take part in nucleophilic attack at the carbonyl group, and it is basic—the $pK_a$ of diisopropylamine is about 35, which is plenty basic enough to deprotonate next to any carbonyl group. The lithium enolate is stable at low temperature (–78°C) but reactive enough to be useful. Lithium enolates are the most commonly used stable enolate equivalents in chemistry.

**Silyl enol ethers**

Second only to lithium enolates in usefulness are silyl enol ethers. Silicon is less electropositive than lithium, and silyl enol ethers are more stable, and less reactive, than lithium enolates. They are made by treating an enolate with a silicon electrophile. Silicon electrophiles invariably react with enolates at the oxygen atom firstly because they are hard (see pp. 357 and 467) and secondly because of the very strong Si–O single bond. The most common silicon electrophile is trimethylsilyl chloride ($\text{Me}_3\text{SiCl}$), an intermediate made industrially in bulk and used to make the NMR standard tetramethylsilane ($\text{Me}_4\text{Si}$).

Silicon–oxygen bonds are so strong that silicon reacts with carbonyl compounds on oxygen even without a strong base to form the enolate: the reaction probably goes through the small amount of enol present in neutral solution and just needs a weak base (Et$_3$N) to remove the proton from the product. An alternative view is that the silicon reacts with oxygen first, and the base just converts the oxonium ion to the silyl enol ether. Both mechanisms are given below—either might be correct. This is one of the two best ways to make a stable enol derivative from virtually any enolizable carbonyl compound.

Silyl enol ethers can also be made from lithium enolates just by treating them with trimethylsilyl chloride.

Occasionally, it can be useful to run this reaction in reverse, generating the lithium enolate from the silyl enol ether. This can be done with methyl lithium, which takes part in nucleophilic substitution at silicon to generate the lithium enolate plus tetramethylsilane.
We shall be returning to silyl enol ethers and lithium enolates later in the book, but for the moment you should view them simply as enol derivatives that are stable enough to be formed quantitatively from carbonyl compounds before being used in further reactions.

**Enol and enolate reactions at oxygen: preparation of enol ethers**

You have just seen that silyl enol ethers are easy to make. But, if enolate ions have most of their negative charge on the oxygen atom, it ought to be possible to make ordinary, carbon-based ethers from them too. It is—but only under strange conditions. Normally, enols and enolate ions prefer to react with alkylating agents (such as alkyl halides) at carbon, as we shall see in Chapter 25. If enolate ions are prepared with potassium bases in dipolar aprotic solvents (such as dimethyl sulfoxide, DMSO) that cannot solvate the oxygen anion, and are treated with dimethylsulfate or trimethyloxonium ion—powerful methylating agents that react best with charged atoms—some at least of the enol ether is formed. The Me₃O⁺ ion is found in the stable (though reactive) compound trimethyloxonium tetrafluoroborate, or Meerwein's salt, Me₃O⁺BF₄⁻. This compound and dimethylsulfate, Me₂SO₄, are hard electrophiles with highly polarized C–O bonds which therefore react with the enolate at hard O rather than soft C.

The yield in this reaction is about 60–70% of enol ether, the rest being mainly C-alkylated product. A more reliable method for making an enol ether is the acid-catalysed decomposition of an acetal in the strict absence of water:

The reaction starts as though the acetal were being hydrolysed, but there is no water to continue the hydrolysis, so a proton is lost instead. In other words, with no suitable nucleophile for S₈₁ substitution, E₁ elimination takes place.
These enol ethers are rather unstable, particularly towards acid-catalysed hydrolysis (as described in the next section) and are not as useful as the silyl enol ethers. We shall next look at the enol-like reactions of both groups of enol ethers.

### Reactions of enol ethers

#### Hydrolysis of enol ethers

Enols have an OH group and are alcohols of a sort. Normal alcohols form stable ethers that are difficult to convert back to the alcohol. Powerful reagents such as HI or BBr₃ are required and these reactions were discussed in Chapter 15. The reaction with HI is an $S_{N}2$ attack on the methyl group of the protonated ether and that is why a good nucleophile for saturated carbon, such as iodide or bromide, is needed for the reaction. Enol ethers, by contrast, are relatively unstable compounds that are hydrolysed back to the carbonyl compound simply with aqueous acid—dilute HCl or H₂SO₄, for example.

\[
\text{HI} \quad \rightarrow \quad \text{S}_{N}2 \quad \text{Me} \quad \rightarrow \quad \text{OH}
\]

Why the big difference? The reason is that the enol ether can be protonated at carbon using the delocalization of the oxygen lone pair in the enol derivative to produce a reactive oxonium ion.

\[
\text{Me} \quad \rightarrow \quad \text{O} \quad \rightarrow \quad \text{Me}
\]

This oxonium ion could be attacked on the methyl group in the same way that the ordinary ether was attacked.

\[
\text{X} \quad \rightarrow \quad \text{Me} \quad \rightarrow \quad \text{O} \quad \rightarrow \quad \text{Me}
\]

We wouldn’t really expect this reaction to happen much faster than the same reaction on an ordinary ether, so there must be another better and faster mechanism. That mechanism is attack on the $\pi$ bond instead of attack on the $\sigma$ bond.

\[
\text{X} \quad \rightarrow \quad \text{Me} \quad \rightarrow \quad \text{O} \quad \rightarrow \quad \text{Me}
\]

In aqueous acid the nucleophile $X^{-}$ is just water and we find ourselves in the middle of the mechanism of hydrolysis of acetals (Chapter 11, p. 226). The oxonium ion is an intermediate common to both mechanisms.

\[
\text{OH}_{2} \quad \rightarrow \quad \text{Me} \quad \rightarrow \quad \text{O} \quad \rightarrow \quad \text{Me}
\]
A similar reaction occurs when enol ethers react with alcohols in acid solution and in the absence of water, but now we are starting in the middle of the acetal hydrolysis mechanism and going the other way, in the direction of the acetal. A useful example is the formation of THP (tetrahydropyranyl) derivatives of alcohols from the enol ether dihydropyran. You will see THP derivatives of alcohols being used as protecting groups in Chapter 23.

![Diagram of THP formation from enol ether](image)

Silyl enol ethers hydrolyse by a slightly different mechanism, although the first step is the same—protonation at carbon using the lone pair on oxygen. We have already seen how easy it is to attack silicon with nucleophiles, especially those with oxygen or a halogen as the nucleophilic atom. This tips the balance towards attack by water at silicon for the next step.

![Diagram of silyl enol ether hydrolysis](image)

The aldehyde is formed immediately. What happens to the other product illustrates again just how easy nucleophilic substitution at silicon can be. Two of these compounds combine together to give a disilyl ether, called a disiloxane.

![Diagram of disiloxane formation](image)

### Reactions of silyl enol ethers with halogen and sulfur electrophiles

In comparison with other ethers, enol ethers of all kinds are rather unstable. As alkenes they are also more reactive than normal alkenes because of the lone pair of electrons on the oxygen atom. They react with electrophiles like bromine or chlorine on the α carbon atom, behaving like enol derivatives and not like alkenes.

Electrophilic attack occurs at the α carbon atom and the halide ion released in this step then attacks the silicon atom to release the product and a molecule of Me₃SiX, which will be hydrolysed during the work-up.

![Diagram of silyl enol ether reaction with halogen electrophiles](image)

This procedure avoids the difficulties we outlined earlier in the direct halogenation of aldehydes and ketones. It allows the preparation of haloacetates on the less substituted side of the carbonyl group, for instance.

![Diagram of haloacetate formation](image)

---

See the discussion of THP protecting groups on p. 550 for the mechanism of this reaction, although you should be able to work it out without looking there!

**Pyrans**

Pyran is a six-membered oxygen-containing heterocyclic ring system with two double bonds. It is not aromatic although compounds like pyrones are. The compound with only one double bond is therefore dihydropyran, and the saturated ring system is tetrahydropyran.
A similar method with the good soft electrophile PhSCI allows sulfonylation next to the carbonyl group.

\[
\begin{align*}
\text{R} & \overset{\text{Me}_3\text{SiCl}}{\text{Et}_3\text{N}} \text{O} & \overset{\text{PhSCI}}{\text{R}} & \text{SiMe}_3 \text{Cl} & \text{SPh} \\
\text{R} & \overset{\text{H}}{\text{O}} & \overset{\text{H}}{\text{SiMe}_3} & \text{SPh} & \text{R} \\
\end{align*}
\]

The mechanism is very similar: the electrophilic sulfur atom attacks the \( \alpha \) carbon atom of the silyl enol ether, releasing a chloride ion that removes the Me\(_3\)Si group from the intermediate.

\[
\begin{align*}

To conclude

You have now seen how enols and enolates react with electrophiles based on hydrogen (deuterium), carbon, halogens, silicon, sulfur, and nitrogen. What remains to be seen is how new carbon–carbon bonds can be formed with alkyl halides and carbonyl compounds in their normal electrophilic mode. These reactions are the subject of Chapters 25–26, but next we look at the ways aromatic compounds react with electrophiles. You will see similarities with the behaviour of enols.

Introduction: enols and phenols

In the last chapter you saw that many ketones have a nucleophilic ‘alter ego’ known as an enol tautomer. Formation of the enol tautomer is catalysed by acid or by base, and because the ketone and enol are in equilibrium, enolization in the presence of D₂O can lead to replacement of the protons in the α positions of ketones by deuterium atoms. This is what happens to pentan-3-one in acidic D₂O:

![Enolization and deuteration process](image)

Because the enolization and deuteration process can be repeated, eventually all of the α-protons are replaced by deuterium.

The way this ketone is deuterated provides evidence that its enol form exists, even though the keto/enol equilibrium greatly favours the ketone form at equilibrium. In this chapter we shall be discussing similar reactions of a compound that exists entirely in its enol form. That very stable enol is phenol and its stability is a consequence of the aromaticity of its benzene ring.

Online support. The icon in the margin indicates that accompanying interactive resources are provided online to help your understanding: just type www.chemtube3d.com/clayden/123 into your browser, replacing 123 with the number of the page where you see the icon. For pages linking to more than one resource, type 123-1, 123-2 etc. (replacing 123 with the page number) for access to successive links.
The proton NMR spectrum for phenol is shown below. Before reading any further cover up the rest of this page and make sure you can assign the spectrum.

The next spectrum is the proton NMR after shaking phenol with acidic D₂O. Most of the peaks have almost disappeared because the H atoms have been replaced with D. Only one signal remains the same size, and even that is simplified because it has lost any coupling to adjacent protons it may have had previously.

The signal that remains is the 2H signal for the protons in the 3 and 5 positions of the aromatic ring, so the product must be the one shown in the margin. We can explain why by using the same mechanism we used with the ketone on the previous page. Phenol is deuterated in the same way as other enols, except that the final product remains in the very stable, aromatic, enol form rather than reverting to the keto form. The first step (after initial replacement of the OH with OD) is addition of D₃O⁺ to the enol.

Now this cation could lose the D from oxygen to leave a ketone (brown arrow below), or it could lose the proton from carbon to leave the phenol (orange arrows below). Alternatively, it could just lose the D and go back to the starting material, which is why there is an equilibrium arrow in the scheme above.

Our spectrum tells us that three ring protons are replaced by D—the ones at the 2, 4, and 6 positions. It's not hard to see how the same process on the other side of the OH group replaces the proton at C-6. But how does the D at position 4 get there? The enol of phenol is conjugated, and we can push the curly arrows one stage further, like this:
The end product on treating phenol with $^3\text{D}O^+$ has the protons in the 2, 4, and 6 positions (that is, the ortho and para positions) substituted by deuterium. $^3\text{D}O^+$ is an electrophile, and the overall process is called electrophilic substitution. It is a reaction characteristic of not only phenol but of other aromatic compounds, and it forms the subject of this chapter.

When aromatic compounds react with electrophiles they generally do so by electrophilic aromatic substitution.

**Benzene and its reactions with electrophiles**

We’ll start with the most straightforward aromatic compound: benzene. Benzene is a planar symmetrical hexagon with six trigonal (sp$^2$) carbon atoms, each having one hydrogen atom in the plane of the ring. All the bond lengths are 1.39 Å (compare C–C 1.47 Å and C=C 1.33 Å). All the $^{13}\text{C}$ shifts are the same ($\delta_{\text{C}}$ 128.5).

The special stability of benzene (aromaticity) comes from the six $\pi$ electrons in three molecular orbitals formed by the overlap of the six atomic $p$ orbitals on the carbon atoms. The energy levels of these orbitals are arranged so that there is exceptional stability in the molecule (a notional 140 kJ mol$^{-1}$ over a molecule with three conjugated double bonds), and the shift of the six identical hydrogen atoms in the NMR spectrum ($\delta_{\text{H}}$ 7.2) is evidence of a ring current in the delocalized $\pi$ system.

**Drawing benzene rings**

Benzene is symmetrical and the structure with a circle in the middle best represents this. However, it is impossible to draw curly arrow mechanisms using this representation so we shall usually make use of the Kekulé form with three double bonds. This does not mean that we think the double bonds are localized! It makes no difference which Kekulé structure you draw—any mechanism can be equally well drawn using either.

Aromatic substituents

A reminder (see pp. 36 and 416) of the names we give to the positions around a benzene ring relative to any substituent:

<table>
<thead>
<tr>
<th>Positions</th>
<th>Abbreviations</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>ortho</td>
</tr>
<tr>
<td>2</td>
<td>meta</td>
</tr>
<tr>
<td>3</td>
<td>para</td>
</tr>
</tbody>
</table>

Ortho, meta, and para are sometimes abbreviated to $o$, $m$, and $p$. The concept of aromaticity is central to this chapter: we will elaborate considerably on the introduction to aromatic compounds we presented in Chapter 7.
In substituted aromatic molecules such as phenol, the C–C bond lengths in the ring are no longer exactly the same. However, it is still all right to use either representation, depending on the purpose of the drawing. With some aromatic compounds, such as naphthalene, it does matter which Kekulé structure you use as there is some alternation of bond lengths. Only the first Kekulé representation shows that the central bond is the strongest and shortest in the molecule and that the C1–C2 bond is shorter than the C2–C3 bond. And if a circle in a ring indicates six $\pi$ electrons, then two circles suggests 12, even though naphthalene has only 10, making this representation less satisfactory too.

**Electrophilic attack on benzene and on cyclohexene**

Simple alkenes, including cyclohexene, react rapidly with electrophiles such as bromine or peroxy-acids (Chapter 19). Bromine gives the product of *trans* addition, peracids give epoxides by *cis* addition. Under the same conditions benzene reacts with neither reagent.

![Diagram](image)

Benzene can, however, be persuaded to react with bromine if a Lewis acid catalyst such as AlCl$_3$ is added. The product contains bromine but is not from either *cis* or *trans* addition.

The bromine atom has replaced an atom of hydrogen, so this is a substitution reaction. The reagent (Br$_2$) is electrophilic and benzene is aromatic so the reaction is *electrophilic aromatic substitution*, the subject of this chapter.

We can compare the bromination of cyclohexene and of benzene directly.

![Diagram](image)

The intermediate in both reactions is a cation but the first (from cyclohexene) adds an anion while the second (from benzene) loses a proton so that the aromatic system can be restored. Notice also that neutral bromine reacts with the alkene but the cationic AlCl$_3$ complex is needed to get reaction with benzene. Bromine itself is a very reactive electrophile. It is indeed a dangerous compound and should be handled only with special precautions. Even so it does not react with benzene. It is difficult to get benzene to react with anything.

**Benzen is very unreactive**

- It combines only with very reactive (usually cationic) electrophiles.
- It gives substitution and not addition products.

**The intermediate in electrophilic aromatic substitution is a delocalized cation**

We will return again and again to this mechanism of electrophilic aromatic substitution during this chapter. In its most general form the mechanism has two stages: attack by an electrophile to give an intermediate cation and loss of a proton from the cation to restore the aromaticity.
The cationic intermediate is, of course, unstable compared with the starting materials or the product. But it is nonetheless stabilized by delocalization. The arrows below show how the positive charge can be delocalized to the two ortho positions and to the para position, or can be drawn as a single delocalized structure with partial (dotted) bonds and about one-third of a positive charge (+) at three atoms.

It’s very important to note that although it is delocalized, this cation is not aromatic: there is no cyclic array of p orbitals because the ring contains a single tetrahedral (sp$^3$ hybridized) carbon atom. We have emphasized this tetrahedral atom by drawing in the hydrogen atom at the point of substitution—the one that will be lost when aromaticity is regained. We suggest that when you write mechanisms for electrophilic aromatic substitution you do the same. Given this loss of aromaticity, it is not surprising that formation of the cationic intermediate is the rate-determining step of an electrophilic aromatic substitution.

**How do we know the cationic intermediate exists?**

In strong acid, the electrophile is a proton and it is actually possible to observe this cationic intermediate. The trick is to pick a non-nucleophilic and non-basic counterion $X^-$, such as SbF$_5$. In this octahedral anion, the central antimony atom is surrounded by the fluorine atoms with the negative charge spread over all seven atoms. The protonation is carried out using FSO$_3$H and SbF$_5$ at –120 °C. A similar trick was described in Chapter 15 as a means to show the existence of simple carbocations as intermediates in the $S_{N1}$ mechanism.

Under these conditions it is possible to record the $^1$H and $^{13}$C NMR spectra of the cation. The shifts show that the positive charge is spread over the ring but is greatest (i.e. the electron density is least) at the ortho and para positions. Using the data for the $^1$H and $^{13}$C NMR shifts ($\delta_H$ and benzene $\delta_C$, respectively), a charge distribution can be calculated that closely matches the predictions of the curly arrows.

**Nitration of benzene**

Now we’ve introduced to you the general principles of electrophilic aromatic substitution we need to delve into the details a little more and show you some real reactions of benzene. In each case, a powerful cationic electrophile is needed to persuade the unreactive benzene to act as a nucleophile.
We’ll start with nitration, the introduction of a nitro \((\text{NO}_2)\) group. Nitration requires very powerful reagents, the most typical being a mixture of concentrated nitric and sulfuric acids.

Sulfuric acid is the stronger acid and it produces the powerful electrophile \(\text{NO}_2^+\) by protonating the nitric acid so that a molecule of water can leave.

The nitronium ion \((\text{NO}_2^+)\) is linear—it’s isoelectronic with \(\text{CO}_2\), with an sp-hybridized nitrogen atom at the centre. It’s this nitrogen that is attacked by benzene, breaking one of the N=O bonds to avoid a five-valent nitrogen.

**Sulfonation of benzene**

Benzene reacts slowly with sulfuric acid alone to give benzenesulfonic acid. One molecule of sulfuric acid protonates another and loses a molecule of water. Notice the similarity with the first step of the nitration above.

The cation produced is very reactive and attacks benzene by the same mechanism we have seen for bromination and nitration—slow addition to the \(\pi\) system followed by rapid loss of a proton to regenerate aromaticity.

The product contains the sulfonic acid group \(\text{–SO}_2\text{OH}\). Sulfonic acids are strong acids, about as strong as sulfuric acid itself. They are stronger than HCl, for example, and can be isolated...
from the reaction mixture as their crystalline sodium salts if an excess of NaCl is added. Not many compounds react with NaCl!

![Sulfonation with H₂SO₄ or SO₃ in H₂SO₄ converts aromatic compounds (ArH) into aromatic sulfonic acids (ArSO₂OH). The electrophile is SO₃ or SO₃H⁺.](image1)

### Alkyl and acyl substituents can be added to a benzene ring by the Friedel–Crafts reaction

So far we have added heteroatoms only—bromine, nitrogen, or sulfur. Adding a carbon substituent to a reluctant aromatic nucleophile requires reactive carbon electrophiles and that means carbocations. In Chapter 15 you learned that any nucleophile, however weak, will react with a carbocation in the S₈₁ reaction: benzene rings are no exception. The classic S₈₁ electrophile is the tert-butyl cation, which is generated from tert-butanol with acid.

![Interactive mechanism for Friedel–Crafts alkylation](image2)

![Interactive mechanism for Friedel–Crafts acylation](image3)

This is, in fact, an unusual way to carry out such reactions. The Friedel–Crafts alkylation, as this is known, usually involves treating benzene with a tertiary alkyl chloride and the Lewis acid AlCl₃. Rather in the manner of the reaction with bromine, AlCl₃ removes the chlorine atom from t-BuCl and releases the t-Bu cation for the alkylation reaction.

![Interactive mechanism for Friedel–Crafts acylation](image4)

We have not usually bothered with the base that removes the proton from the intermediate. Here it is chloride ion as the by-product is HCl, so you can see that even a very weak base will do. Anything, such as water, chloride, or other counterions of strong acids, will do this job well enough and you need not in general be concerned with the exact agent.

A more important variation of this reaction is the Friedel–Crafts acylation with acid chlorides and AlCl₃. Aluminium chloride behaves with acyl chlorides much as it does with alkyl chlorides—it removes chloride to leave behind a cation. In this case the cation is a linear acylim ion, with the carbocation stabilized by the adjacent oxygen lone pair. When the acylim ion attacks the benzene ring it gives an aromatic ketone: the benzene ring has been acylated.

Charles Friedel (1832–1899), a French chemist, and James Crafts (1839–1917), an American mining engineer, both studied with Wurtz and then worked together in Paris, where in 1877 they discovered the reaction which now carries their names.
The acylation is better than the alkylation because it does not require any particular structural feature in the acyl chloride—R can be almost anything. In the alkylation step it is essential that the alkyl group can form a cation, otherwise the reaction does not work very well. In addition, for reasons we are about to explore, the acylation stops cleanly after one reaction whereas the alkylation often gives mixtures of products.

- **Friedel–Crafts reactions**

Friedel–Crafts alkylation with t-alkyl chlorides and Lewis acids (usually AlCl₃) gives t-alkyl benzenes. The more reliable Friedel–Crafts acylation with acid chlorides and Lewis acids (usually AlCl₃) gives aryl ketones.

**Summary of electrophilic substitution on benzene**

This completes our preliminary survey of the most important reactions in aromatic electrophilic substitution. We shall switch our attention to the benzene ring itself now and see what effects various types of substituent have on these reactions. During this discussion we will return to each of the main reactions and discuss them in more detail. Meanwhile, we conclude this introduction with an energy profile diagram for a typical substitution.

Since the first step involves the temporary disruption of the aromatic π system, and is therefore rate determining, it must have the higher-energy transition state. The intermediate is unstable and has a much higher energy than either the starting material or the products, close to that of the transition states for its formation and breakdown. The two transition states will be similar in structure to the intermediate and we shall use the intermediate as a model for the important first transition state.

- **Summary of the main electrophilic substitutions on benzene**

This argument is based on the Hammond postulate, which suggests that structures close in energy that transform directly into each other are also similar in structure. For more on this, see Chapter 39.
Electrophilic substitution on phenols

We started this chapter by comparing phenols with enols and now we return to phenols and look at electrophilic substitution in full detail. You will find that the reaction is much easier than it was with benzene itself because phenols are like enols and the same reactions (bromination, nitration, sulfonation, and Friedel–Crafts reactions) occur more easily. There is a new question too: the positions round the phenol ring are no longer equivalent—so where does substitution take place?

Phenols react rapidly with bromine

Benzene does not react with bromine except with Lewis acid catalysis. Phenols react in a very different manner: no Lewis acid is needed, the reaction occurs very rapidly, and the product contains three atoms of bromine in specific positions. All that needs to be done is to add bromine dropwise to a solution of phenol in ethanol. Initially, the yellow colour of the bromine disappears but if, when the colour just remains, water is added, a white precipitate of 2,4,6-tribromophenol is formed.

The product shows that bromination has occurred at the para position and at both ortho positions. What a contrast to benzene! Phenol reacts three times, without catalysis, at room temperature. Benzene reacts once, and needs a Lewis acid to make the reaction go at all. The difference is, of course, the enol nature of phenol. The non-bonding lone pair of electrons at oxygen contribute to a much higher-energy HOMO than the low-energy bonding electrons in a benzene ring. We should let our mechanism show this. Starting in the para position:

Notice that we start the chain of arrows with the lone pair electrons on the OH group and push them through the ring so that they emerge at the para position to attack the bromine molecule. The benzene ring is acting as a conductor, allowing electrons to flow from the OH group to the bromine molecule.

Now the reaction is repeated, but this time at one of the two equivalent ortho positions:

Again the lone pair electrons on the OH group are fed through the benzene ring to emerge at the ortho position. A third bromination in the remaining ortho position—you could draw the mechanisms for this as practice—gives the final product 2,4,6-tribromophenol.
If you want to put just one bromine atom into a phenol, you must work at low temperature (<5 °C) and use just one equivalent of bromine. The best solvent is the rather dangerously inflammable carbon disulfide (CS₂), the sulfur analogue of CO₂. Under these conditions, para-bromophenol is formed in good yield as the main product (which is why we started the mechanism for bromination of phenol in the para position). The minor product is ortho-bromophenol.

\[
\text{HO} \quad \text{Br} \\
1 \times \text{Br}_2 \quad \text{CS}_2, <5 \, ^\circ\text{C} \\
\text{HO} \\
\text{4-bromophenol} \quad 85\% \text{ yield}
\]

The OH group is said to be ortho, para-directing towards electrophiles. No substitution occurs in either meta position. We can understand this by looking at the curly arrow mechanisms or by looking at the molecular orbitals. In Chapter 20 (p. 453) we looked at the π system of an enolate and saw how the electron density is located mainly on the end atoms (the oxygen and the carbon). In phenol it is the ortho and para positions that are electron-rich (and, of course, the oxygen itself). We can show this using curly arrows.

The curly arrows actually give an indication of the electron distribution in the HOMO of the molecule. The reason is that the HOMO has large coefficients at alternate atoms, just as the allyl anion had large coefficients at its ends but not in the middle (Chapter 7).

**NMR can give us some confirmation of the electron distribution**

The ¹H NMR shifts of phenol give us an indication of the electron distribution in the π system. The more electron density that surrounds a nucleus, the more shielded it is and so the smaller the shift (see Chapter 13). All the chemical shifts for the ring protons in phenol are smaller than those for benzene (7.26 ppm), which means that overall there is greater electron density in the ring. There is little difference between the ortho and the para positions: these are where the electron density is greatest and hence these are the sites for electrophilic attack. The chemical shift at the meta positions is not significantly different from those in benzene—this is where the electron density is lowest.

**Electrophilic attack on phenols**

OH groups on benzene rings are ortho, para-directing and activating.

You will get the right product if you start your arrows at a lone pair on the OH group.

**Oxygen substituents activate a benzene ring**

To brominate phenol, all we had to do was to mix bromine and phenol—if we do this with benzene itself, nothing happens. We therefore say that, relative to benzene, the OH group in phenol activates the ring towards electrophilic attack. The OH group is both activating and ortho, para-directing. Other groups that can donate electrons also activate and direct ortho, para. Anisole (methoxybenzene) is the ‘enol ether’ equivalent of phenol. It reacts faster than benzene with electrophiles.
2,4-D

The multiple chlorination of another oxygen-substituted compound, phenoxyacetic acid, leads to a useful product. Chlorination with two equivalents of chlorine provides 2,4-dichlorophenoxy acetic acid, which is the herbicide 2,4-D. The oxygen substituent again activates the ring and directs the chlorination to the ortho and para positions.

![Chemical Structure of Phenoxyacetic Acid and 2,4-Dichlorophenoxyacetic Acid]

Nitration of phenol is also very fast and can be problematic under the usual nitration conditions (conc. HNO₃, conc. H₂SO₄) because concentrated nitric acid oxidizes phenols. The solution is to use dilute nitric acid. The concentration of NO₂⁺ will be small but that does not matter with such a reactive benzene ring.

![Chemical Structure of Nitrophenols]

The product is a mixture of ortho- and para-nitrophenol from which the ortho compound can be separated by steam distillation. A strong intramolecular hydrogen bond reduces the availability of the OH group for intermolecular hydrogen bonding so the ortho compound has a lower boiling point.

**Paracetamol from a phenol**

The remaining para-nitrophenol is used in the manufacture of the painkiller paracetamol (also known as acetaminophen).

![Chemical Structure of Paracetamol]

The phenoxide ion is even more reactive towards electrophilic attack than phenol. It manages to react with such weak electrophiles as carbon dioxide. This reaction, known as the Kolbe–Schmitt process, is used industrially to prepare salicylic acid (2-hydroxybenzoic acid), a precursor in making aspirin.

![Chemical Structure of Salicylic Acid and Aspirin]
The O⁻ substituent is ortho, para-directing but the electrophilic substitution step with CO₂ gives mostly the ortho product. There must be some coordination between the sodium ion and the oxygen atoms of both the phenoxide and CO₂ that delivers the electrophile to the ortho position.

![Diagram of sodium phenoxide and sodium salicylate coordination](image)

**A nitrogen lone pair activates even more strongly**

Aniline (phenylamine) is even more reactive towards electrophiles than phenols, phenyl ethers, or phenoxide ions. Because nitrogen is less electronegative than oxygen, the lone pair is higher in energy and so even more available to interact with the π system than is the lone pair on oxygen. Reaction of aniline with bromine is very vigorous and rapidly gives 2,4,6-tri-bromoaniline. The mechanism is very similar to the bromination of phenol so we show only one ortho substitution to remind you of how it goes.

![Diagram of aniline bromination](image)

The ¹H NMR spectrum of aniline supports the increased electron density in the π system—the aromatic protons are even less deshielded than those of phenol as a result.

Just how good nitrogen is in donating electrons into the π system is shown by comparing the relative rates for the bromination of benzene, methoxybenzene (anisole), and N,N-dimethylaniline.

**Making aromatic amines less reactive**

The high reactivity of aniline can actually be a problem. Suppose we wanted to put just one bromine atom onto the ring. With phenol, this is possible (p. 480)—if bromine is added slowly to a solution of phenol in carbon disulfide solution and the temperature is kept below 5 °C, the main product is para-bromophenol. Not so if aniline is used—the main product is the triply substituted product.
How then could we prevent oversubstitution from occurring? What we need is a way to make aniline less reactive by preventing the nitrogen lone pair from interacting so strongly with the π system of the ring. Fortunately, it is very simple to do this. In Chapter 8 (p. 175) we saw how the nitrogen atom in an amide is much less basic than a normal amine because it is conjugated with the carbonyl group. This is the strategy that we will use here—simply acylate the amine to form an amide. The lone pair electrons on the nitrogen atom of the amide are conjugated with the carbonyl group as usual but their delocalization into the benzene ring is weaker than in the amine. The amide nitrogen donates less electron density into the ring, so the electrophilic aromatic substitution is more controlled. The lone pair is still there, but its power is tamed. Reaction still occurs in the ortho and para positions (mainly para) but it occurs once only.

After the reaction, the amide can be hydrolysed (here, with aqueous acid) back to the amine.

- Anilines react rapidly with electrophiles to give polysubstituted products. Their amide derivatives react in a more controlled manner to give para-substituted products.

**Selectivity between ortho and para positions**

Phenols and anilines react in the ortho and/or para positions for electronic reasons. These are the most important effects in deciding where an electrophilic substitution will occur on a benzene ring. When it comes to choosing between ortho and para positions we need to consider steric effects as well. You will have noticed that we have seen one ortho selective reaction—the formation of salicylic acid from phenol—and several para selective reactions such as the bromination of an amide just discussed.

If the reactions occurred merely statistically, we should expect twice as much ortho as para product because there are two ortho positions. However, we should also expect more steric hindrance in ortho substitution since the new substituent must sit closely beside the one already there. With large substituents, such as the amide, steric hindrance will be significant and it is not surprising that we get more para product.

There is another effect that decreases the amount of ortho substitution, and that is the inductive electron-withdrawing effect of an electronegative substituent. As you’ve seen, oxygen and nitrogen, although they are electronegative, activate the ring towards attack by donating π electron density from their lone pairs. At the same time, the C–O or C–N σ bond is polarized back towards the O or N atom—in other words, they donate electron density to the π system but withdraw electron density from the σ framework. This is inductive electron withdrawal—it affects the atoms nearest the O or N atom the most, and has the effect of decreasing the likelihood that attack will happen in the ortho positions.
Alkyl benzenes also react at the ortho and para positions

This is what happens when toluene (methylbenzene) meets bromine:

\[
\begin{align*}
\text{Me} & \quad \text{Me} & \quad \text{Br} \\
\text{Me} & \quad \text{Br} & \quad \text{Me} \\
\text{Br} & \quad \text{Me} & \quad \text{Me}
\end{align*}
\]

about 60% ortho  about 35% para  about 5% meta

Toluene reacts 4000 times faster than benzene (this may sound like a lot, but the rate constant for N,N-dimethylaniline is \(10^{14}\) times greater), and the electrophile attacks mostly the ortho and para positions. These two observations together suggest that the methyl groups may be increasing the electron density in the \(\pi\) system of the benzene ring, specifically in the ortho and para positions, rather like a weaker version of an OR group. The \(^1\)H NMR chemical shifts for toluene (see margin) do suggest that there is slightly more electron density in the para position than in the meta positions. All the shifts are smaller than those of benzene (but not by much) and the shielding is much less than it is in phenols or anilines.

The methyl group donates electrons weakly by conjugation. In phenol, a lone pair on oxygen is conjugated with the \(\pi\) system. In toluene there is no lone pair but one of the C–H \(\sigma\) bonds can still interact with the \(\pi\) system in a similar way. This interaction is known as \(\sigma\) conjugation. Just as the conjugation of the oxygen lone pair increases the electron density at the ortho and para positions, so too does \(\sigma\) conjugation, but far less so.

\(\sigma\) conjugation also means toluene's \(\pi\) electrons—its HOMO—become slightly higher in energy than those of benzene. It is best to regard alkyl benzenes as rather reactive benzenes, and to draw mechanisms using their \(\pi\) electrons as the nucleophile, like this:

\[
\begin{align*}

\text{Me} & \quad \text{E} & \quad \text{H}
\end{align*}
\]

Electrophilic attack occurs on alkyl benzenes so that the positive charge ends up on the carbon bearing the alkyl group. This carbon is tertiary, making the cation there more stable. This condition is fulfilled if toluene is attacked at the ortho position, as shown above, but also at the para position, because in both cases the positive charge is delocalized onto the same three carbons atoms.

If, on the other hand, the electrophile were to attack at the meta position, the charge would end up delocalized over three carbon atoms, none of which are tertiary, so no stabilization by the alkyl group is possible. The situation is no worse than that of benzene, but given that toluene reacts some \(10^3\) times faster than benzene at the ortho and para positions these reactions win out. Nonetheless, unlike phenol, toluene does give trace amounts of meta-substituted products.
Protonating toluene with a superacid

On p. 475 we described how to observe the cationic intermediate in electrophilic substitution reactions of benzene by protonation in an NMR tube using a superacid. In benzene the cation which forms is symmetrical. Doing the same experiment with toluene leads to protonation in the para position.

The ortho (to the Me group) carbon has a shift ($\delta$ 139.5) only 10 ppm greater than that of benzene ($\delta$ 129.7) but the ipso and meta carbons have the very large shifts that we associate with cations. The charge is mainly delocalized to these carbons but the greatest charge is at the ipso carbon.

The sulfonation of toluene

Direct sulfonation of toluene with concentrated sulfuric acid gives a mixture of ortho and para sulfonic acids from which about 40% of toluene para sulfonic acid can be isolated as the sodium salt.

We shall use SO₃ as the electrophile in this case and draw the intermediate with the charge at the ipso carbon to show the stabilization from the methyl group.

You met the para-toluene sulfonate group (tosylate, OTs) as an important leaving group if you want to carry out an Sₘ₂ reaction on an alcohol (Chapter 15, p. 349) and the acid chloride (tosyl chloride, TsCl) needed to make tosylates can be made from the acid in the usual way (p. 215) with PCl₅. It can also be made directly from toluene by sulfonation with chlorosulfonic acid CISO₂OH. This reaction favours the ortho sulfonyl chloride, which is isolated by distillation.
No other acid is needed because chlorosulfonic acid is a very strong acid indeed and protonates itself to give the electrophile. This explains why OH is the leaving group rather than Cl and why chlorosulfonation rather than sulfonation is the result.

In drawing the mechanism we can again get the positive charge onto the tertiary ipso atom. No treatment with NaCl is needed in this reaction as the major product (the ortho acid chloride) is isolated by distillation.

It is fortunate that the ortho acid chloride is the major product in the chlorosulfonation because it is needed in the synthesis of saccharin, the first of the non-fattening sweeteners. The formation of the sulfonamide is like that of an ordinary amide, but the oxidation of the methyl group with potassium permanganate is probably new to you. It’s a rather vigorous reaction, but one which very usefully turns toluene derivatives into benzoic acid derivatives.

Alkylbenzenes react with electrophiles faster than benzene and give mixtures of ortho- and para-substituted products.

**Electron-withdrawing substituents give meta products**

So far, all of the substituted benzene rings we have considered have carried substituents capable of donating electron density to the ring: despite being electronegative atoms, oxygen and nitrogen have lone pairs which conjugate with the ring’s $\pi$ system; a similar but weaker effect results from $\sigma$ conjugation from a methyl group. Two consequences arise from these substituents: the ring becomes more reactive than benzene, and substitution takes place in the ortho and para positions.

So what happens with groups which pull electron density away from the ring? Such a group is the trimethylammonium substituent: the nitrogen is electronegative but unlike in aniline this electronegativity is not offset by donation of a lone pair—the nitrogen is tetrahedral and no longer has one to donate. Nitration of the phenyltrimethyl ammonium ion yields mainly...
the *meta* product. And it does so slowly too—this nitration proceeds about $10^7$ times more slowly than that of benzene.

The same thing happens with the CF$_3$ group. The three very electronegative fluorine atoms polarize the C–F bonds so much that the Ar–C bond is polarized too. Nitration of trifluoromethylbenzene gives a nearly quantitative yield of *meta* nitro compound.

Draw the mechanism for this reaction and you see the reason for the switch to *meta* selectivity.

If, on the other hand, the electrophile were to attack the *ortho* or *para* position (the hypothetical reaction *para* to CF$_3$ is shown below) then the carbon next to CF$_3$ would have to carry a positive charge, which would be destabilized by the electron withdrawal, making this a high-energy intermediate.

Think of it this way: the electron-deficient ring would really rather not react with an electrophile (hence the slower rate) but if it has to (because the electrophile is so reactive) then it takes the least bad course of keeping the positive charge away from the electron-withdrawing groups—and that means *meta* substitution.

**Some substituents withdraw electrons by conjugation**

Aromatic nitration is important because it is a convenient way of adding a nitrogen substituent to the ring and because it stops cleanly after one nitro group has been added. Double nitration of benzene is possible but stronger conditions must be used—fuming nitric acid instead of normal concentrated nitric acid—and the mixture must be refluxed at around 100 °C.
The second nitro group is introduced \textit{meta} to the first: evidently the nitro group is deactivating and \textit{meta}-directing.  

The nitro group is conjugated with the $\pi$ system of the benzene ring and is strongly electron withdrawing—and it withdraws electrons specifically from the \textit{ortho} and \textit{para} positions. We can use curly arrows to show this:

![Curly arrows showing electron withdrawal from \textit{ortho} and \textit{para} positions](image)

The nitro group withdraws electron density from the $\pi$ system of the ring thereby making the ring less reactive towards an electrophile. Since more electron density is removed from the \textit{ortho} and \textit{para} positions, the least electron-deficient position is the \textit{meta} position. Hence the nitro group is \textit{meta} directing. In the nitration of benzene, it is much harder to nitrate a second time and, if we insist, the second nitro group goes in \textit{meta} to the first.

Other reactions go the same way: bromination of nitrobenzene gives \textit{meta}-bromonitrobenzene in good yield. The combination of bromine and iron powder provides the necessary Lewis acid catalyst ($\text{FeBr}_3$) while the high temperature needed for this unfavourable reaction is easily achieved as the boiling point of nitrobenzene is over 200 °C.

![Bromination reaction](image)

In drawing the mechanism it is best to draw the intermediate and to emphasize that the positive charge must not be delocalized to the carbon atom bearing the nitro group.

![Mechanism showing delocalization of intermediate cation](image)

Nitro is just one of a number of groups that are also deactivating towards electrophiles and \textit{meta} directing because of electron withdrawal by conjugation. Others include carbonyl groups (aldehydes, ketones, esters, etc.), nitriles, and sulfonates. The $^1\text{H}$ NMR shifts of rings carrying these substituents confirm that they remove electrons principally from the \textit{ortho} and \textit{para} positions.
Points to note:

- Each of the compounds contains the unit Ph–X=Y, where Y is an electronegative element, usually oxygen.
- In each compound, all the protons have larger chemical shifts than benzene because the electron density at carbon is less.
- The protons in the meta position have the smallest shift and so the greatest electron density.

Nitro is the most electron-withdrawing of these groups and some of the other compounds are nearly as reactive (in the meta position, of course) as benzene itself. It is easy, for example, to nitrate methyl benzoate and the m-nitro ester can then be hydrolysed to meta-nitrobenzoic acid very easily.

One group of substituents remains and they are slightly odd. They are ortho, para-directing but they are also deactivating. They are the halogens.

**Halogens show evidence of both electron withdrawal and donation**

So far we have steered clear of the reactions of halogenated derivatives of benzene. Before we explain their reactions, have a look at the table, which shows the rates of nitration of fluoro, chloro, bromo, and iodobenzene relative to benzene itself, and also gives an indication of the products formed in each case.

<table>
<thead>

</tr>
</tbody>
</table>

We’ll come back to this table a few times in the next page or so, but the first thing to note is that all the halobenzenes react more slowly than benzene itself. Evidently, electron withdrawal by the electronegative halogen deactivates the ring towards attack. But the second thing that should strike you is that, unlike the deactivating groups we have just been discussing, halogens are ortho, para-directing—very few meta-nitrated products are formed.

The only way this makes sense is if there are two opposing effects: electron donation by conjugation and electron withdrawal by induction. The halogen has three lone pairs, one of which may conjugate with the ring just like in phenol or aniline. Yet the conjugation is much less good than in phenol or aniline, for one of two reasons. When Cl, Br, or I is the substituent, the problem is size: the 2p orbitals from the carbon atoms overlap poorly with the bigger p orbitals from the halogen (3p for chlorine, 4p for bromine, and 5p for iodine). This size mismatch is clearly illustrated by comparing the reactivities of aniline and chlorobenzene:
chlorine and nitrogen have approximately the same electronegativity, but aniline is much more reactive than chlorobenzene because of the better overlap between the carbon and nitrogen 2p orbitals. Fluorine 2p orbitals are the right size to overlap well with the carbon 2p orbitals, but now there is another problem: the orbitals of fluorine are much lower in energy than the orbitals of carbon since fluorine is so electronegative.

So, all four halogens are less good at donating electrons to the ring than an OH or NH$_2$ group, but not only are the halobenzenes less reactive than phenol or aniline, they are even less reactive than benzene itself. Now, when we looked at aniline and phenol, we didn’t worry about any electron withdrawal by induction, even though both oxygen and nitrogen are of course rather electronegative. Electron donation from their N and O lone pairs is evidently much more important. But with the conjugation in the halobenzenes already weak, inductive electron withdrawal takes over as the dominant factor in determining reactivity.

With all this in mind, how would you expect fluorobenzene to react? Most electron density is removed first from the ortho positions by induction, then from the meta positions, and then from the para position. Any conjugation of the lone pairs on fluorine with the π system would increase the electron density in the ortho and para positions. Both effects favour the para position and this is where most substitution occurs. But is the ring more or less reactive than benzene? This is hard to say and the honest answer is that sometimes fluorobenzene is more reactive in the para position than benzene (for example, in proton exchange and in acetylation—see later) and sometimes it is less reactive than benzene (for example, in nitration, as shown by the table above). In all cases, fluorobenzene is significantly more reactive than the other halobenzenes. We appreciate that this is a rather surprising conclusion, but the evidence supports it. For example, fluorobenzene reacts with bromine and an iron catalyst (it does need a catalyst: it is not as reactive as phenol) at only –20 °C to give the para-bromo derivative.

Let’s now look back in bit more detail at the table above. We can now also explain two other features of the results:

- The percentage of the ortho product increases from fluorobenzene to iodobenzene. We might have expected the amount to decrease as the size of the halide increases because of increased steric hindrance at the ortho position but this is clearly not the case. Instead the greater inductive effect of the more electronegative atoms (F, Cl) withdraws electron density mostly from the ortho positions, lessening their reactivity.
- The rates of the reactions fall into two pairs and follow a ‘U-shaped’ sequence: fluorobenzene nitrates most quickly, followed closely by iodobenzene; chloro-, and bromobenzene nitrate at around half these rates. Chlorine and bromine suffer because both are quite electronegative and neither has good lone pair overlap: in fluorine, overlap is good; in iodine, electronegativity is much less.

In practical terms, it is usually possible to get high yields of para products from electrophilic substitution reactions of halobenzenes. Both nitration and sulfonation of bromobenzene give enough material to make the synthesis worthwhile. Although mixtures of products are always bad in a synthesis, electrophilic aromatic substitution is usually simple to carry out on a large enough scale to make separation of the major product, ideally by crystallization, a workable method. A 68% yield of sodium p-bromobenzenesulfonate can be achieved by recrystallization of the sodium salt from water and a 70% yield of p-bromonitrobenzene by separation from the ortho isomer by recrystallization from EtOH.
Summary of directing and activating effects

Now we can summarize the stage we have reached in terms of activation and direction.

Two or more substituents may cooperate or compete

The directing effects of two or more substituents can work with or against one another. Bromoxynil and ioxynil are contact herbicides especially used in spring cereals to control weeds resistant to other weedkillers, and both are synthesized from p-hydroxybenzaldehyde by double halogenation. The aldehyde directs meta and the OH group directs ortho: both effects work together to promote bromination or iodination at the same two positions.

In other cases substituents compete by directing to different positions. The antioxidant BHT (p. 58) is made from 4-methylphenol (known as p-cresol) by a Friedel–Crafts alkylation. Usually, both the methyl and OH groups are ortho, para directors. The para positions are obviously both blocked, but the positions ortho to each of the groups are different. Since the –OH group is much more powerfully directing than the methyl group it ‘wins’ and directs the electrophile (a t-buty1 cation) ortho to itself.

In this case the t-buty1 cation is made from the alkene and protic acid; alternative reagents would be t-butanol with protic acid or t-buty1 chloride with AlCl₃.

Even a ‘watered-down’ activating group like the amide –NHCOMe, which provides an extra pair of electrons, will ‘win’ over a deactivating group or an activating alkyl group. Bromination of this amide goes ortho to the –NHCOMe group but meta to the methyl group.
When looking at any compound where competition is an issue it is sensible to consider electronic effects first and then steric effects. For electronic effects, in general, any activating effects are more important than deactivating ones. For example, the aldehyde below has three groups—two methoxy groups that direct ortho and para and an aldehyde that directs meta.

Despite the fact that the aldehyde group withdraws electron density from positions 2 and 6, C6 is still the position for nitration. The activating methoxy groups dominate electronically and the choice is really between C2, C5, and C6. Now consider steric factors: reaction at C2 or C5 would lead to three adjacent substituents. Substitution occurs at position 6.

Some problems and some opportunities

You’ve seen plenty of electrophilic aromatic substitution reactions in this chapter that are reliable and widely used—bromination and nitration, for example. But others pose problems:

- Friedel–Crafts alkylation works only when the intermediate cation is stable, so how do we add an n-alkyl chain to an aromatic ring?
- There is no good way of introducing an oxygen electrophile to an aromatic ring, so how do we make Ar–O bonds?
- Electron-donating groups always direct ortho, para, so how do we put in a group meta to, for example, an amino group?

We will consider some answers to these questions in this last section of this chapter.

A closer look at Friedel–Crafts chemistry

Reactions such as nitration and sulfonation add a very deactivating substituent. They usually stop cleanly after a single substitution unless there is also a strongly activating substituent. Even then it may be possible to stop after a single substitution. Weakly electron-withdrawing substituents like the halogens can be added once, but multiple substitution is common when the starting arene carries strongly activating substituents like OH and NH₂.

Two reasons to avoid a Friedel–Crafts alkylation

When electron-donating substituents are added, multiple substitution is always a threat. The principal reaction where multiple substitution is a genuine problem is the Friedel–Crafts alkylation reaction. Here’s an example: preparation of diphenylmethane from benzene and benzyl chloride is a useful reaction but the product has two benzene rings, each more reactive than benzene itself. A 50% yield is the best we can do and that requires a large excess of benzene to ensure that it competes successfully for the reagent with the reactive, electron-rich product.
Multiple substitution is just one of the potential pitfalls of Friedel–Crafts alkylations. The other is important to be aware of too: **Friedel–Crafts alkylations work well only with stable cations.** This is what happens when we try a Friedel–Crafts reaction with \( n \)-propyl chloride.

Recall from Chapter 15 that primary halides don’t form cations easily, so the Friedel–Crafts reaction with \( n \)-propyl chloride has to go via an \( S_N2 \) mechanism.

So where does the major product of the reaction come from? The three carbons are arranged not as an \( n \)-propyl group but as an iso-propyl group: a *rearrangement* has occurred. This is the mechanism:

- Rerangement (migration of green H) leads to isopropyl benzene

The green hydrogen migrates to allow a secondary rather than a primary alkyl cation to be formed, and iso-propylbenzene results. This leaves us with a problem: how can you add primary alkyl groups to benzene rings?

**The solution: use Friedel–Crafts acylation instead**

We can kill two birds with one stone here: both problems common to the Friedel–Crafts alkylation are solved when the acylation is used instead. Firstly, the product of the acylation is a ketone: the reaction introduces a deactivating, electron-withdrawing, conjugating carbonyl group to the ring, so the product is less reactive than the starting material. Reaction will stop cleanly after one acylation. Here’s benzene reacting with propionyl chloride.

If we want the ketone then all well and good. But a simple reduction also allows us to get the alkylated product—this compound (trivially called propiophenone) is reduced to
propylbenzene using any of a number of reduction methods, for example zinc amalgam in hydrochloric acid.

\[
\text{Zn/Hg} \quad \text{HCl} \quad \rightarrow \quad n\text{-propylbenzene}
\]

The reduction of a Friedel–Crafts acylation product like this always gives an \( n \)-alkylbenzene, exactly the sort of compound that causes the problems in Friedel–Crafts alkylation. Friedel–Crafts acylations also work well when anhydrides are used in the place of acid chlorides. The acylium ion is formed in the same way:

\[
\begin{align*}
\text{R} & \quad \text{O} \\
\text{O} & \quad \text{O} \\
\text{AlCl} & \quad \text{Cl} \\
\text{Cl} & \quad \text{AlCl}_3 \\
\text{R} & \quad \text{O} \\
\text{O} & \quad \text{O} \\
\text{AlCl}_3 & \quad + \\
\text{acylium ion} & \quad \text{anhydride}
\end{align*}
\]

If a cyclic anhydride is used, the product is a keto-acid.

\[
\begin{align*}
\text{O} & \quad \text{O} \\
\text{O} & \quad \text{O} \\
\text{OH} & \quad \text{OH} \\
\text{+} & \quad 2.2 \text{ equivalents} \\
\text{2-benzoylpropanoic acid} & \quad \text{succinic anhydride} (\text{the anhydride of butanedioic acid, or succinic acid}) \\
\text{AlCl}_3 & \quad \text{3-benzoylpropanoic acid}
\end{align*}
\]

Reduction of the ketone can give a simpler carboxylic acid, but we can go one step further and do another acylation—because the reaction is intramolecular, it goes even with just a strong acid (phosphoric acid): the strong acid makes the OH into a good leaving group (water) and the acylium ion is again an intermediate.

\[
\begin{align*}
\text{O} & \quad \text{O} \\
\text{O} & \quad \text{O} \\
\text{Ph} & \quad \text{OH} \\
\text{Zn / Hg} & \quad \text{HCl} \\
\text{4-phenylbutanoic acid} & \quad \text{H}_3\text{PO}_4 \\
\text{O} & \quad \text{O}
\end{align*}
\]

\begin{itemize}
\item The advantages of acylation over alkylation
\item Two problems in Friedel–Crafts alkylation do not arise with acylation.
\item The acyl group in the product withdraws electrons from the \( \pi \) system, making multiple substitutions harder. Indeed, if the ring is too deactivated to start off with, Friedel–Crafts acylation may not be possible at all—nitrobenzene is inert to Friedel–Crafts acylation and is often used as a solvent for these reactions.
\item Rearrangements are also no longer a problem because the electrophile, the acylium cation, is already relatively stable.
\item The acyl groups of the products can be reduced to primary alkyl groups, which are impossible to introduce cleanly by Friedel–Crafts alkylation.
\end{itemize}

### Exploiting the chemistry of the nitro group

The nitro group is remarkably useful in a number of ways:

\begin{itemize}
\item It is easy to introduce by nitration chemistry (p. 476).
\item Unlike most N- or O-based functional groups, it is a meta director (p. 488).
\item It can be reduced to an amino group.
\item It can be replaced with other substituents using diazonium chemistry.
\end{itemize}
You have met the first two of these features, but the last two may be new to you. An aromatic nitro group is easy to turn into an amino group—a number of reagents will do this, but the most common are tin in dilute HCl or hydrogenation with a palladium catalyst supported on charcoal (written as Pd/C).

\[
\text{NO}_2 \xrightarrow{\text{H}_2, \text{Pd/C} \text{ or Sn, dil. HCl}} \text{NH}_2
\]

This simple transformation is extremely important because it turns the meta-directing nitro group into an ortho, para-directing amino group (although as you saw on p. 483, the amino group may need ‘taming’ to make its reactivity useful). The sequence of nitration—reduction allows us to introduce a useful NH\textsubscript{2} equivalent into an aromatic molecule, and can let us make otherwise difficult-to-form meta-substituted amino compounds.

\[
\begin{align*}
\text{HNO}_3 + \text{H}_2\text{SO}_4 & \rightarrow \text{NO}_2 \\
\text{H}_2, \text{Pd/C} \text{ or Sn, dil. HCl} & \rightarrow \text{NH}_2
\end{align*}
\]

The reduction to an amino group also opens up the possibility of replacing the nitrogen substituent completely, by converting it first to a diazonium group. Treatment of an amine with nitrous acid converts it to an unstable diazonium salt, whose mechanism of formation and chemistry we will discuss in the next chapter. Not surprisingly, diazonium salts very readily lose nitrogen gas, and this substitution of N\textsubscript{2} by a nucleophile opens yet more opportunities to compounds derived from nitrobenzene derivatives. It also involves nucleophilic substitution at the aromatic ring, which forms the subject of the next chapter.

\[
\text{NH}_2 \xrightarrow{\text{NaNO}_2, \text{HCl, 0 °C}} \text{diazonium salt} \xrightarrow{\text{H}_2\text{O}} \text{OH}
\]

**Further reading**

**Check your understanding**

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Conjugate addition and nucleophilic aromatic substitution

Alkenes conjugated with carbonyl groups

To start this chapter, let us take you back to one of the first reactions we introduced: nucleophilic addition to carbonyl groups. Here are two examples, both of which give products which you should fully expect. We've included details of the IR spectra of the products to confirm firstly that the product has no carbonyl group and secondly that the alkene is still there.

Now let’s tweak the conditions: we repeat the first reaction at a higher temperature, and we add to the second a small amount of a copper salt. Now the products are different:
Both products A and B have kept their carbonyl group (IR peak at 1710–1715 cm$^{-1}$) but have lost the C=C. Yet A, at least, is unquestionably an addition product because it contains a C≡N peak at 2250 cm$^{-1}$.

Well, the identities of A and B are revealed here: they are the products of addition, not to the carbonyl group, but to the C=C bond. Here’s a mechanism, for both reactions of cyanide: firstly the direct addition to C=O and secondly addition to the C=C bond.

This type of reaction, where a nucleophile adds to a C=C double bond, is called conjugate addition, and this chapter is about the sorts of alkenes (and arenes) that do this kind of thing. We will also explain how such small differences in reaction conditions (temperature, or the presence of CuCl) manage to change the outcome so dramatically.

But first we need to place these conjugate additions into context. As you found out in Chapter 19, alkenes are nucleophilic. Almost regardless of their substituents, they react with electrophiles such as bromine to form adducts in which the π bond of the alkene has been replaced by two σ bonds.

Even when the alkene is conjugated with an electron-withdrawing group, as the alkenes on the last page were, bromine addition still occurs, although less readily. Never lose sight of this: alkenes are nucleophilic.

But as we have just seen, this last type of alkene also reacts with nucleophiles (such as cyanide, Grignard reagents, and, as you see below, more besides), and we now need to consider why.

**Conjugated alkenes can be electrophilic**

Conjugate additions occur only when the C=C double bond is immediately adjacent to the C=O group. They don’t occur to C=C bonds that aren’t conjugated (see the box on p. 501 for an illustration of this).

Compounds with double bonds adjacent to a C=O group are known as α,β-unsaturated carbonyl compounds. Many α,β-unsaturated carbonyl compounds have trivial names, and some are shown here. Some classes of α,β-unsaturated carbonyl compounds also have names such as ‘enone’, made up of ‘ene’ (for the double bond) + ‘one’ (for ketone).
The α and β refer to the distance of the double bond from the C=O group: the α carbon is the one next to C=O (not the carbonyl carbon itself), the β carbon is one further down the chain, and so on.

Most types of nucleophiles can be made to undergo conjugate additions with α,β-unsaturated carbonyl compounds, and seven examples are shown below. Note that many of these nucleophiles would not add to a simple carbonyl group: we will explain why shortly. Conjugate addition is also known as Michael addition, and the reactive α,β-unsaturated carbonyl compounds shown here are often known as Michael acceptors.

Nucleophile:
- cyanide
  \[ \text{KCN} + \text{C} = \text{O} \rightarrow \text{NC} = \text{O} \]
- amines
  \[ \text{Et}_2\text{NH} + \text{C} = \text{O} \rightarrow \text{Et}_2\text{N} = \text{O} \]
- alcohols
  \[ \text{MeOH} + \text{C} = \text{O} \rightarrow \text{MeO} = \text{O} \]
- thiols
  \[ \text{MeSH} + \text{C} = \text{O} \rightarrow \text{MeS} = \text{O} \]
- bromide
  \[ \text{HBr} + \text{C} = \text{O} \rightarrow \text{Br} = \text{O} \]
- chloride
  \[ \text{HCl} + \text{C} = \text{O} \rightarrow \text{Cl} = \text{O} \]
- benzene
  \[ \text{C} + \text{C} \rightarrow \text{C} = \text{O} \]

The reason that α,β-unsaturated carbonyl compounds react differently is conjugation, the phenomenon we discussed in Chapter 7. There we introduced you to the idea that bringing two π systems (two C=C bonds, for example, or a C=C bond and a C=O bond) close together leads to a stabilizing interaction. It also leads to modified reactivity, because the π bonds no longer react as independent functional groups but as a single, conjugated system.

- Conjugation makes alkenes electrophilic
  - C=C double bonds are nucleophilic
  - C=C double bonds conjugated with carbonyl groups can be electrophilic
Termite self-defence and the reactivity of alkenes
Soldier termites of the species Schedorhinotermes lamanianus defend their nests with secretions of the enone shown below (compound 1), which is very effective at taking part in conjugate addition reactions with thiols (RSH). This makes it highly toxic, since many important biochemicals carry SH groups (one is described on p. 508). The worker termites of the same species—who build the nests—need to be able to avoid being caught in the crossfire, so they are equipped with an enzyme that allows them to reduce compound 1 to compound 2. This still has a double bond, but the double bond is completely unreactive towards nucleophiles because it is not conjugated with a carbonyl group. The workers escape unharmed.

Alkenes conjugated with carbonyl groups become polarized
To show why alkenes conjugated with carbonyl groups behave differently from unconjugated alkenes, we use curly arrows to indicate delocalization of the π electrons over the four atoms in the conjugated system. Both representations are extremes, and the true structure lies somewhere in between, but the polarized structure indicates why the conjugated C=C bond is electrophilic and why the β carbon is attacked by nucleophiles.

Polarization is detectable spectroscopically
IR spectroscopy provides us with evidence for polarization in C=C bonds conjugated to C=O bonds. An unconjugated ketone C=O absorbs at 1715 cm$^{-1}$ while an unconjugated alkene C=C absorbs (usually rather weakly) at about 1650 cm$^{-1}$. Bringing these two groups into conjugation in an α,β-unsaturated carbonyl compound leads to two peaks at 1675 and 1615 cm$^{-1}$, respectively, both quite intense. The lowering of the frequency of both peaks is consistent with a weakening of both π bonds (notice that the polarized structure has only single bonds where the C=O and C=C double bonds were). The increase in the intensity of the C=C absorption is consistent with polarization brought about by conjugation with C=O: a conjugated C=C bond has a significantly larger dipole moment than its unconjugated cousins.

The polarization of the C=C bond is also evident in the $^{13}$C NMR spectrum, with the signal for the sp$^2$ carbon atom furthest from the carbonyl group moving downfield relative to an unconjugated alkene to about 140 ppm, and the signal for the other double bond carbon atom staying at about 120 ppm.

Molecular orbitals control conjugate additions
We have spectroscopic evidence that a conjugated C=C bond is polarized, and we can explain this with curly arrows, but the actual bond-forming step must involve movement of electrons from the HOMO of the nucleophile to the LUMO of the unsaturated carbonyl compound. This example is an efficient (the reaction happens even at 0 °C) addition to acrolein (propanal) with methoxide as the nucleophile.
But what does this LUMO look like? It will certainly be more complicated than the $\pi^*$ LUMO of a simple carbonyl group. The nearest thing you have met so far (in Chapter 7) are the orbitals of butadiene ($\text{C}=$ $\text{C}$ conjugated with $\text{C}=$ $\text{C}$), which we can compare with the $\alpha,\beta$-unsaturated aldehyde acrolein ($\text{C}=$ $\text{C}$ conjugated with $\text{C}=$ $\text{O}$). The orbitals in the $\pi$ systems of butadiene and acrolein are shown here. They are different because acrolein’s orbitals are perturbed (distorted) by the oxygen atom (Chapter 4). You need not be concerned with exactly how the sizes of the orbitals are worked out, but for the moment just concentrate on the shape of the LUMO, the orbital that will accept electrons when a nucleophile attacks.

In the LUMO, the largest coefficient is on the $\beta$ carbon of the $\alpha,\beta$-unsaturated system, shown with an asterisk. And it is here, therefore, that nucleophiles attack. In the reaction you have just seen, the HOMO is the methoxide oxygen’s lone pair, so this will be the key orbital interaction that gives rise to the new bond.

The second largest coefficient is on the $\text{C}=\text{O}$ carbon atom, so it’s not surprising that some nucleophiles attack here as well—remember the example right at the beginning of the chapter where you saw cyanide attacking either the double bond or the carbonyl group depending on the conditions of the reaction. We shall next look at some conjugate additions with alcohols and amines as nucleophiles, before reconsidering the question of where the nucleophile attacks.
Conjugate additions have enolates or enols as intermediates

So much for the addition step of the reaction. But the product of this step is of course not the final product of the reaction—it is in fact an enolate. We hope you recognize these species from Chapter 20, where you saw them being made by treating carbonyl compounds with base. Conjugate addition is another way of generating an enolate, and as with all enolates, protonation gives back a carbonyl compound. The proton has to come from somewhere, so conjugate additions are usually done in protic solvents (such as alcohols or water). Here is another example with an alcohol as the nucleophile:

\[
\begin{align*}
\text{O} & \quad \text{O} \\
\text{H} & \quad \text{H} \\
\text{O} & \quad \text{O} \\
\text{H} & \quad \text{H} \\
\text{O} & \quad \text{O} \\
\text{H} & \quad \text{H} \\
\text{NaOH} & \quad \text{H}_2\text{O}, -5 °\text{C} \\
\end{align*}
\]

60% yield

In alkaline solution, a small amount of alkoxide is produced (the \( pK_a \) of an alcohol is slightly higher than that of water), which attacks the \( \text{C} = \text{C} \) double bond in a conjugate addition. The product is an enolate, which is protonated by water to give the final aldehyde, and regenerates hydroxide as it does so: only a catalytic amount of base is required for this type of reaction.

Amines are good nucleophiles for conjugate addition. In the reaction below, aqueous dimethylamine is used in a sealed system to stop the amine evaporating (dimethylamine is a gas even at room temperature).

\[
\begin{align*}
\text{O} & \quad \text{O} \\
\text{N} & \quad \text{Me}_2\text{NH} \\
\text{Me} & \quad \text{Me} \\
\text{50 °C, 1 h} \\
\end{align*}
\]

50% yield

Amines are neutral nucleophiles, and the amine itself provides a proton for the enolate.

If you survey the initial overview of conjugate additions on p. 500 you will see that several take place under acidic conditions. Treatment of this \( \alpha,\beta \)-unsaturated ketone with HCl, for example, gives a chloroketone. The first step must be protonation of the carbonyl group, which makes the enone even more electrophilic by giving it a positive charge. Chloride attacks the \( \beta \) carbon to give an enol.
All that remains to happen now is tautomerism of the enol to its keto form by proton transfer from O to C.

**Conjugate addition or direct addition to the carbonyl group?**

We have shown you several examples of conjugate additions using various nucleophiles and α,β-unsaturated carbonyl compounds, but we haven’t yet addressed one important question. When do nucleophiles do conjugate addition (also called 1,4-addition) and when do they add directly to the carbonyl group (1,2-addition)? Several factors are involved—they are summarized here, and we will spend the next section of this chapter discussing them in turn.

The way that nucleophiles react depends on:
- the conditions of the reaction
- the nature of the α,β-unsaturated carbonyl compound
- the type of nucleophile.

**Reaction conditions**

The very first conjugate addition reaction in this chapter depended on the conditions of the reaction. Treating an enone with cyanide and an acid catalyst at low temperature gives a cyanohydrin by direct attack at C=O, while heating the reaction mixture leads to conjugate addition. What is going on?

We’ll consider the low-temperature reaction first. As you know from Chapter 6, it is quite normal for cyanide to react with a ketone under these conditions to form a cyanohydrin. You also know from Chapter 6 that cyanohydrin formation is reversible. Even if the equilibrium for cyanohydrin formation lies well over to the side of the products, there will always be a small amount of starting enone remaining. Most of the time, this enone will react to form more cyanohydrin and, as it does, some cyanohydrin will decompose back to enone plus cyanide—such is the nature of a dynamic equilibrium. But every now and then—at a much slower rate—the starting enone will undergo a *conjugate addition* with the cyanide.
Now we have a different situation: conjugate addition is essentially an irreversible reaction, so once a molecule of enone has been converted to conjugate addition product, its fate is sealed: it cannot go back to enone again. Very slowly, therefore, the amount of conjugate addition product in the mixture will build up. In order for the enone–cyanohydrin equilibrium to be maintained, any enone that is converted to conjugate addition product will have to be replaced by reversion of cyanohydrin to enone plus cyanide. Even at room temperature, we can therefore expect the cyanohydrin to be converted bit by bit to conjugate addition product. This may take a very long time, but reaction rates are faster at higher temperatures, so at 80 °C this process does not take long at all and, after a few hours, the cyanohydrin has all been converted to conjugate addition product.

The contrast between the two products is this: the cyanohydrin is formed faster than the conjugate addition product, and is known as the product of kinetic control (or the kinetic product), but the conjugate addition product is the more stable compound and is the product of thermodynamic control (or the thermodynamic product). Typically, kinetic control involves lower temperatures and shorter reaction times, which ensures that only the fastest reaction has the chance to occur. And, typically, thermodynamic control involves higher temperatures and long reaction times to ensure that even the slower reactions have a chance to occur, and all the material is converted to the more stable compound.

---

**Kinetic and thermodynamic control**

- The product that forms faster is called the kinetic product.
- The product that is the more stable is called the thermodynamic product.

Similarly,

- Conditions that give rise to the kinetic product are called kinetic control.
- Conditions that give rise to the thermodynamic product are called thermodynamic control.

---

Why is direct addition faster than conjugate addition? Well, although the carbon atom β to the C=O group carries some positive charge, the carbon atom of the carbonyl group carries more, and so electrostatic attraction for the charged nucleophiles will encourage it to attack the carbonyl group directly rather than undergo conjugate addition.

And why is the conjugate addition product the more stable? In the conjugate addition product, we gain a C–C σ bond, losing a C=σ bond, but keeping the C=O π bond. With direct addition, we still gain a C–C bond, but we lose the C=O π bond and keep the C=O σ bond. C=O π bonds are stronger than C=C π bonds, so the conjugate addition product is more stable.

Practically, then, to get conjugate addition to occur you just have to give the reaction plenty of energy and maybe plenty of time to find its way to the most stable product. Here’s an example: note the temperature!

---

**Structural factors**

So far we have shown you conjugate additions mainly of α,β-unsaturated aldehydes and unsaturated α,β-ketones. You won’t be at all surprised to learn, however, that unsaturated acids, esters, amides, and nitriles—in fact all carboxylic acid derivatives—can also take part in conjugate addition reactions. Two examples, an amide and an ester, are shown on the right below. But notice how the selectivity of these reactions depends on the structure of the unsaturated compound: compare the way butyllithium adds to this α,β-unsaturated aldehyde and α,β-unsaturated amide. Both additions are irreversible, and BuLi attacks the reactive carbonyl group of the aldehyde, but prefers conjugate addition to the less reactive amide. Similarly, ammonia reacts with this acyl chloride to give an amide product that derives from direct...
addition to the carbonyl group, while with the ester it undergoes conjugate addition to give an amine.

\[
\begin{align*}
\text{1. BuLi, } & \ -70 ^\circ \text{C to } +20 ^\circ \text{C} \\
\text{2. } H_2O
\end{align*}
\]

In both of these cases, the site of nucleophilic attack is determined simply by reactivity: the more reactive the carbonyl group, the more direct addition to \( C=O \) will result. The most reactive carbonyl groups, as you saw in Chapter 10, are those that are not conjugated with \( O \) or \( N \) (as they are in esters and amides), and particularly reactive are acyl chlorides and aldehydes. In general, the proportion of direct addition to the carbonyl group follows the reactivity sequence in the margin.

Sodium borohydride is a nucleophile that you have seen reducing simple aldehydes and ketones to alcohols, but it will also do conjugate addition reactions. Which of the alternatives actually takes place depends on the reactivity of the \( C=O \) group. \( NaBH_4 \) usually reacts with \( \alpha,\beta \)-unsaturated aldehydes to give alcohols by direct addition to the carbonyl group.

Quite common with ketones, however, is the outcome below.

The borohydride has reduced not only the carbonyl group but the double bond as well. In fact, it’s the double bond that’s reduced first in a conjugate addition, followed by addition to the carbonyl group.

Luche reduction
It is possible to force \( NaBH_4 \) to attack only the \( C=O \) group by adding \( CeCl_3 \) to the reaction mixture. This modification is known as the Luche reduction, after its discoverer.

For esters and other less reactive carbonyl compounds conjugate addition is the only reaction that occurs because \( NaBH_4 \) doesn’t reduce esters or amides.

The nature of the nucleophile: hard or soft
Among the best nucleophiles of all at doing conjugate addition are thiols, the sulfur analogues of alcohols. In this example, the nucleophile is thiophenol (phenol with the \( O \) replaced by \( S \)).
Remarkably, no acid or base catalyst is needed (as it was with the alcohol additions), and the product is obtained in 94% yield under quite mild reaction conditions.

So what’s so special about a thiol? As you’ve seen already, attraction between nucleophiles and electrophiles is governed by two related interactions—electrostatic attraction between positive and negative charges and orbital overlap between the HOMO of the nucleophile and the LUMO of the electrophile. Successful reactions usually result from a combination of both, but sometimes reactivity can be dominated by one or the other. The dominant factor, be it electrostatic or orbital control, depends on the nucleophile and electrophile involved. Nucleophiles containing small, electronegative atoms (such as O or Cl), which we call ‘hard’, tend to react under predominantly electrostatic control, while ‘soft’ nucleophiles containing larger atoms (including the sulfur of thiols, but also P, I, and Se) are predominantly subject to control by orbital overlap.

The table below divides some nucleophiles into the two categories (plus some that lie in between)—but don’t try to learn it! Rather, convince yourself that the properties of each one justify its location in the table. Most of these nucleophiles you have not yet seen in action, and the most important ones at this stage are indicated in bold type.

Not only can nucleophiles be classified as hard or soft, but electrophiles can too. For example, H⁺ is a very hard electrophile because it is small and charged, while Br₂ is a soft electrophile: its orbitals are diffuse and it is uncharged. You saw Br₂ reacting with an alkene earlier in the chapter, and we explained in Chapter 5 that this reaction happens solely because of orbital interactions: no charges are involved.

**Hard/soft reactivity**

- Reactions of hard species are dominated by charges and electrostatic effects.
- Reactions of soft species are dominated by orbital effects.
- Hard nucleophiles tend to react well with hard electrophiles.
- Soft nucleophiles tend to react well with soft electrophiles.

What has all this to do with the conjugate addition of thiols? Well, an α,β-unsaturated carbonyl compound is unusual in that it has two electrophilic sites, one of which is hard and one of which is soft. The carbonyl group has a high partial charge on the carbonyl carbon and will tend to react with hard nucleophiles, such as organolithium and Grignard reagents, that have a high partial charge on the nucleophilic carbon atom. Conversely, the β carbon of the α,β-unsaturated carbonyl system does not have a high partial positive charge but is the site of the largest coefficient in the LUMO. This makes the β carbon a soft electrophile and likely to react well with soft nucleophiles such as thiols.

**Hard/soft—direct/conjugate addition**

- Hard nucleophiles tend to react at the carbonyl carbon (hard) of an enone.
- Soft nucleophiles tend to react at the β carbon (soft) of an enone and lead to conjugate addition.
Anticancer drugs that work by conjugate addition of thiols

Drugs to combat cancer act on a range of biochemical pathways, but most commonly on processes that cancerous cells need to use to proliferate rapidly. One class attacks DNA polymerase, an enzyme needed to make the copy of DNA that has to be provided for each new cell. Helenalin and vernolepin are two such compounds, and if you look closely at their structure you should be able to spot two α,β-unsaturated carbonyl groups in each. Biochemistry is just chemistry in very small flasks called cells, and the reaction between DNA polymerase and these drugs is simply a conjugate addition reaction between a thiol (the SH group of one of the enzyme’s cysteine residues) and the unsaturated carbonyl groups. The reaction is irreversible and shuts down completely the function of the enzyme.

For this reason any compound capable of conjugate addition is potentially dangerous to living things. Even simple compounds like ethyl acrylate are labelled ‘cancer suspect agents’. They attack enzymes, particularly the DNA polymerase involved in cell division by conjugate addition to thiol and amino groups in the enzyme. Fortunately, we are offered some degree of protection by an important compound present in most tissues. The compound is glutathione, a tripeptide—a compound made from three amino acids. We shall discuss such compounds in more detail later in the book (Chapter 42) but notice for the moment that this compound can be divided into three at the two amide bonds.

Promoting conjugate addition with copper(I) salts

Grignard reagents add directly to the carbonyl group of α,β-unsaturated aldehydes and ketones to give allylic alcohols: you have seen several examples of this, and you can now explain it by saying that the hard Grignard reagent prefers to attack the harder C=O rather than the softer C=C electrophilic centre. Here is a further example—the addition of MeMgBr to a cyclic ketone to give an allylic alcohol, plus, as it happens, some of a diene that arises from this alcohol by loss of water (dehydration). Below this example is the same reaction to which a very small amount (just 0.01 equivalents, that is, 1%) of copper(I) chloride has been added. The effect of the copper is dramatic: it makes the Grignard reagent undergo conjugate addition, with only a trace of the diene.
Organocopper reagents undergo conjugate addition

The copper works by *transmetallating* the Grignard reagent to give an organocopper reagent—simply put, the magnesium is exchanged for copper. Organocoppers are softer than Grignard reagents, and add in a conjugate fashion to the softer C=C double bond. Once the organocopper has added, the copper salt is available to transmetallate some more Grignard, and only a catalytic amount is required.

The organocopper is shown here as ‘Me–Cu’ because its precise structure is not known. But there are other organocopper reagents that also undergo conjugate addition and are much better understood. The simplest result from the reaction of two equivalents of organolithium with one equivalent of a copper (I) salt such as CuBr in ether or THF solvent at low temperature. The lithium cuprates (R₂CuLi) that are formed are not stable and must be used immediately.

The silicon works by reacting with the negatively charged intermediate in the conjugate addition reaction to give a silyl enol ether—a type of molecule we met in Chapter 20. Here is a possible mechanism for a reaction between Bu₂CuLi and an α,β-unsaturated aldehyde in the presence of Me₃SiCl. The silyl enol ether simply hydrolysates to the ketone at the end of the reaction.

Summary: factors controlling conjugate addition

At this point in the chapter it is worthwhile talking stock of the factors controlling the two modes of addition to α,β-unsaturated carbonyl compounds.
Conjugate (1,4 or Michael) vs direct (1,2) addition

<table>

- Unhindered β carbon
- Soft nucleophiles
- Organocoppers or catalytic Cu(I)
- Hard nucleophiles
- Organolithiums, Grignard reagents

Extending the reaction to other electron-deficient alkenes

It’s not only carbonyl-based groups that make alkenes react with nucleophiles rather than the more usual electrophiles. Other electron-withdrawing groups do just the same thing. Here are two examples: a nitrile and a nitro group. These compound classes appeared in Chapter 21 in the context of aromatic substitution reactions where we saw them pulling electron density away from the ring. The same thing happens here.

Unsaturated nitriles and nitro compounds

The simplest conjugated nitrile is acrylonitrile. This compound adds amines readily. No special conditions are needed to encourage attack at C=C rather than C≡N because the nitrile carbon is rather unreactive as an electrophilic centre.

\[ \text{Et}_2\text{NH} \quad \text{Et}_2\text{N}^+ \quad \text{CN}^- \quad \text{MeHN} \quad \text{MeN}^+ \quad \text{CN}^- \]

The amine first attacks the alkene in a typical conjugate addition to make an anion stabilized by being next to the nitrile. The anion can have its charge drawn on C or N: it is delocalized like an enolate. Do not be put off by the odd appearance of the ‘enolate’. The dot between the two double bonds is a reminder that there is a linear sp carbon atom at this point.

Protonation at carbon restores the nitrile and gives the product—an amino-nitrile. The whole process adds a 2-cyano-ethyl group to the amine and is known industrially as cyanoethylation.

With a primary amine, the reaction need not stop at that stage as the product is still nucleophilic and a second addition can occur to replace the second hydrogen atom on nitrogen.
Other elements such as O, S, or P can add too. Phenyl phosphine can undergo a double addition just as in the last example, but alcohols can add only once. If there is competition between a first-row (for example N or O) and a second-row (for example S or P) element, the second-row element normally wins, for the reasons discussed above (p. 507).

The nitro group \((\text{NO}_2)\) is extremely electron-withdrawing—about twice as electron-withdrawing as a carbonyl group. It is also unreactive as an electrophilic centre, which makes conjugate addition to nitro-alkenes a very reliable reaction. In this example, sodium borohydride attacks the \(\text{C}=\text{C}\) bond in a conjugate manner to give an intermediate looking rather like an enolate anion, with a negatively charged oxygen atom conjugated to an \((\text{N}=\text{C})\) double bond. It reacts like an enolate too, picking up a proton on carbon to re-form the nitro group and give a stable product.

**Conjugate substitution reactions**

Just as direct addition to \(\text{C}=\text{O}\) (Chapter 6) becomes substitution at \(\text{C}=\text{O}\) (Chapter 10) when there is a leaving group at the carbonyl carbon, so conjugate addition becomes conjugate substitution if there is a leaving group, such as \(\text{Cl}\), at the \(\beta\) carbon atom. Here is an example: substitution replaces \(\text{Cl}\) with \(\text{OMe}\), just as it would have done in a reaction with an acyl chloride.

As with substitution at \(\text{C}=\text{O}\), this apparently simple reaction does not involve a direct displacement of the leaving group in a single step. The mechanism starts in exactly the same way as for conjugate addition, giving an enol intermediate.

Now the leaving group can be expelled by the enol: the double bond moves back into its original position in an elimination reaction—the sequence is often called an addition–elimination
reaction. The ‘new’ double bond has the more stable \( E \) configuration. In the next example, two consecutive conjugate substitution reactions give a 1,1-diamine.

\[
\begin{align*}
\text{Cl} & \quad \text{O} \\
\text{Cl} & \quad \text{PhNH}_2 \\
\end{align*}
\]

\[ \text{NHPhO} \quad \text{98\% yield} \]

At first sight, the product looks rather unstable—sensitive to water, or traces of acid perhaps. But, in fact, it is remarkably resistant to reaction with both. The reason is conjugation: this isn’t really an amine (or a diamine) at all because the lone pairs of the nitrogen atoms are delocalized through into the carbonyl group, very much as they are in an amide. This makes them less basic, and makes the carbonyl group less electrophilic.

**Conjugate substitution and the synthesis of anti-ulcer drugs**

Just as the cyanide (CN) and nitro (NO\(_2\)) groups can be used to bring about conjugate addition, so also can they initiate conjugate substitution. Examples of these reactions play important roles in the synthesis of two of the most significant drugs in the development of modern medicinal chemistry: the anti-ulcer compounds cimetidine (marketed as Tagamet) and ranitidine (Zantac). We looked at some aspects of the structure of these drugs in Chapter 8 (p. 178) and we are now going to see how conjugate addition is used in their synthesis.

The simple cyanoimine on the left, with two SMe groups as built-in leaving groups, is readily available and reacts with amines to give guanidines in two stages. Each of the reactions is a conjugate substitution. It will be clearer if we draw the reaction with a generalized primary amine RNH\(_2\) first: conjugate addition, exactly as we saw with acrylonitrile, is followed by expulsion of the best leaving group. Thiols are acidic compounds, and MeS\(^-\) is a better leaving group than RNH\(^-\).

The reaction stops cleanly at this point and more vigorous conditions are required to displace the second MeS\(^-\) group. This is because the first product is less reactive than the starting material: the new amino group is electron-donating and conjugation is established between it and the cyano group, deactivating the molecule towards a second conjugate substitution (as shown in the margin). But under more forcing conditions a second and different amine can be introduced and the second MeS\(^-\) group displaced. In the synthesis of cimetidine the second amine is MeNH\(_2\) and the molecule is complete.
Ranitidine’s right-hand portion is made in a similar way from an unsaturated nitro compound. This time the methylamine substitution is done first, followed by addition of the rest of the molecule.

**Nucleophilic epoxidation**

The conjugate substitutions we have just been discussing rely on a starting material containing a leaving group. In this section we are going to look at what happens if the leaving group is not attached to the unsaturated carbonyl compound, but instead is attached to the nucleophile. We shall look at this class of compounds—nucleophiles with leaving groups attached—in more detail in Chapter 38, but for the moment the most important will be hydroperoxide, the anion of hydrogen peroxide.

Hydroperoxide is a good nucleophile because of the **alpha effect**: interaction of the two lone pairs on adjacent oxygen atoms raises the HOMO of the anion and makes it a better and softer nucleophile than hydroxide. Hydroperoxide is also less basic than hydroxide because of the inductive electron-withdrawing effect of the second oxygen atom. Basicity and nucleophilicity usually go hand in hand—not here though. This means that the hydroperoxide anion can be formed by treating hydrogen peroxide with aqueous sodium hydroxide.

This is what happens when this mixture is added to an enone. First, there is the conjugate addition.
But the product is not stable because hydroxide can be lost from the oxygen atom that was the nucleophile. Hydroxide is fine as a leaving group here—after all, hydroxide is lost from enolates in E1cB eliminations, and here the bond breaking is a weak O–O bond. The product is an epoxide.

The electrophilic epoxidizing agents such as \( m \)-CPBA, which you met in Chapter 19, work reliably only with nucleophilic alkenes, and for \( \alpha,\beta \)-unsaturated carbonyl compounds and other electron-deficient alkenes, hydroperoxide—a nucleophilic epoxidizing agent—is often used instead.

There is another significant difference between hydrogen peroxide and \( m \)-CPBA, highlighted by the pair of reactions below.

\( m \)-CPBA epoxidation is stereospecific because the reaction happens in one step. But nucleophilic epoxidation with hydroperoxide is a two-step reaction: there is free rotation about the bond marked in the anionic intermediate, and the more stable, \( trans \)-epoxide results, whatever the geometry of the starting alkene.

**Nucleophilic aromatic substitution**

In this next section we are going to consider reactions related to conjugate substitutions but in which the double bond is part of an aromatic ring. We spent some considerable time in Chapter 21 explaining that aromatic rings are **nucleophilic**: electrophiles attack them, and typical aromatic reactivity is to undergo electrophilic substitution.

In general, nucleophilic substitutions of aromatic halides—such as the one proposed here in which hydroxide is attempting to displace bromide—**do not happen**. You might well ask, ‘Why not?’ The reaction looks all right and, if the ring were saturated, it **would be** all right.

This is an \( S_N^2 \) reaction, and we know (Chapter 15) that attack must occur in line with the C–Br bond from the back, where the largest lobe of the \( \sigma^* \) orbitals lies. That is perfectly all right for the aliphatic ring because the carbon atom is tetrahedral and the C–Br bond is not in the plane of the ring. Substitution of an equatorial bromine goes like this:
But in the aromatic compound, the C–Br bond is in the plane of the ring as the carbon atom is trigonal. To attack from the back, the nucleophile would have to appear inside the benzene ring and invert the carbon atom in an absurd way. This reaction is of course not possible. This is another example of the general rule:

- $S_N2$ at $sp^2$ C does not occur.

If $S_N2$ is impossible, what about $S_N1$? This is possible but very unfavourable unless the leaving group is an exceptionally good one (see below for an example). It would involve the unaided loss of the leaving group and the formation of an aryl cation. All the cations we saw as intermediates in the $S_N1$ reaction (Chapter 15) were planar with an empty $p$ orbital. This cation is planar but the $p$ orbital is full—it is part of the aromatic ring—and the empty orbital is an $sp^2$ orbital outside the ring.

Yet some aromatic compounds do undergo nucleophilic substitution. Just as normally nucleophilic alkenes can be made to undergo conjugate substitution if they carry electron-withdrawing substituents, so normally nucleophilic aromatic rings also become electrophilic if they have the right substituents. The mechanism by which they undergo nucleophilic substitution also closely parallels that of conjugate substitution which you have just seen.

**The addition–elimination mechanism**

Imagine a cyclic $\beta$-fluoro-enone reacting with a secondary amine in a conjugate substitution reaction. The normal addition to form the enolate followed by return of the negative charge to expel the fluoride ion gives the product.

Now imagine just the same reaction with two extra double bonds in the ring. These play no part in our mechanism; they just make what was an aliphatic ring into an aromatic one. Conjugate substitution has become nucleophilic aromatic substitution.

The mechanism involves *addition* of the nucleophile followed by *elimination* of the leaving group—the **addition–elimination mechanism**. It is not necessary to have a carbonyl group—any electron-withdrawing group will do—the only requirement is that the electrons must be able to get out of the ring into this anion-stabilizing group. Here is an example with a para-nitro group.
Everything is different about this example—the nucleophile (HO\(^-\)), the leaving group (Cl\(^-\)), the anion-stabilizing group (NO\(_2\)), and its position (para)—but the reaction still works. The nucleophile is a good one, the negative charge can be pushed through on to the oxygen atom(s) of the nitro group, and chloride is a better leaving group than OH.

**A typical nucleophilic aromatic substitution has:**

- an oxygen, nitrogen, or cyanide nucleophile
- a halide for a leaving group
- a carbonyl, nitro, or cyanide group ortho and/or para to the leaving group.

Since the nitro group is usually introduced by electrophilic aromatic substitution (Chapter 21) and halides direct ortho/para in nitrination reactions, a common sequence is nitrination followed by nucleophilic substitution.

This sequence is useful because the nitro group could not be added directly to give the final product as nitrination would go in the wrong position. The nitrile is meta-directing, while the alkyl group (R) is ortho, para-directing.

Two activating electron-withdrawing groups are better than one and dinitration of chlorobenzene makes a very electrophilic aryl halide. Reaction with hydrazine gives a useful reagent.

**The intermediate in the addition–elimination mechanism**

What evidence is there for intermediates like the ones we have been using in this section? When reactions like this last example are carried out, a purple colour often appears in the reaction mixture and then fades away. In some cases the colour is persistent and thought to be due to the intermediate. Here is an example with RO\(^-\) attacking a nitrated aniline. This intermediate is persistent because neither potential leaving group (NR\(_2\) or OR) is very good.
What is the nature of this intermediate? Well, in essence it is an anion delocalized over five sp² hybridized carbons of a six-membered ring (the sixth, the point at which the nucleophile attacked, is sp³ hybridized). It’s possible to make a simple homologue of such a species by deprotonating cyclohexadiene. Delocalizing the anion generates the three structures below.

You’ve seen before that ¹³C NMR spectra are revealing when it comes to distribution of charge, and the details of the ¹³C NMR spectrum of this anion are shown below, along with those of benzene itself and also of the cation generated by protonating benzene (which, as you will remember from Chapter 21, corresponds to the intermediate generated in electrophilic aromatic substitution).

These results are very striking. The shifts of the meta carbons in both ions are very slightly different from those of benzene itself (about 130 ppm). But the ortho and para carbons in the anion have gone upfield to much smaller shifts, indicating greater electron density. By contrast, ortho and para carbons in the cation have gone downfield to much larger shifts. The differences are very great—about 100 ppm between the cation and the anion! It is very clear from these spectra that the ionic charge is delocalized almost exclusively to the ortho and para carbons in both cases. The alternative structures in the margin show this delocalization.

This means that stabilizing groups, such as nitro or carbonyl in the case of the anion, can only have an effect if they are on carbons ortho or para to the position being attacked by the nucleophile. A good illustration of this is the selective displacement of one chlorine atom out of these two. The chlorine ortho to the nitro group is lost; the one meta is retained.

The mechanism works well if the nucleophile (the anion derived from the thiol) attacks the carbon bearing the chlorine ortho to the nitro group as the negative charge can then be pushed into the nitro group. Satisfy yourself that you cannot do this if you attack the other chlorine position. This is a very practical reaction and is used in the manufacture of a tranquillizing drug.
The leaving group and the mechanism

In the first nucleophilic aromatic substitution that we showed you, we used fluoride ion as a leaving group. Fluoride works very well in these reactions and even such a simple compound as 2-halo-l-nitrophenyl fluoride reacts efficiently with a variety of nucleophiles, as in these examples.

The same reactions happen with the other 2-halo-l-nitrobenzenes but less efficiently. The fluoro-compound reacts about $10^3$–$10^4$ times faster than the chloro or bromo compounds and the iodo compound is even slower.

This ought to surprise you. When we were looking at other nucleophilic substitutions such as those at the carbonyl group or saturated carbon, we never used fluoride as a leaving group! The C–F bond is very strong—the strongest of all the single bonds to carbon—and it is difficult to break. As a consequence, these reactions are not a good prospect:

This reaction is never used: This reaction is rarely used:

So why is fluoride so good in nucleophilic aromatic substitution when the reverse is true with other reactions? You will notice that we have not said that fluoride is a better leaving group in nucleophilic aromatic substitution. It isn’t! The explanation depends on a better understanding of the mechanism of the reaction. We shall use azide ion as our nucleophile because this has been well studied and because it is one of the best.

The mechanism is exactly the same as that we have been discussing all along—a two-stage addition–elimination sequence. In a two-step mechanism, one step is slower and rate determining; the other is unimportant to the rate. You may guess that, in the mechanism for nucleophilic aromatic substitution, it is the first step that is slower because it disturbs the aromaticity. The second step restores the aromaticity and is faster. The effect of fluoride, or any other leaving group, can only come from its effect on the first step. How good a leaving group it might be does not matter: the rate of the second step—the step where fluoride leaves—has no effect on the overall rate of the reaction.

Fluoride accelerates the first step through its inductive effect. It is the most electronegative element of all and it stabilizes the anionic intermediate, assisting the acceptance of electrons by the benzene ring.
**The activating anion-stabilizing substituent**

We have used nitro groups very extensively so far because they are the best at stabilizing the anionic intermediate. Others that work include carbonyl, cyanide, and sulfur-based groups such as sulfoxides and sulfones. A direct comparison of the different groups \( Z \) that can assist the displacement of bromide (by the secondary amine piperidine in this example) is shown in the margin.

All the compounds react more slowly than the nitro compound. We have already mentioned (Chapters 8 and 21) the great electron-withdrawing power of the nitro group—here is a new measure of that power. The sulfone reacts 18 times slower, the nitrile 32 times slower, and the ketone 80 times slower.

Nitro is the best activating group, but the others will all perform well, especially when combined with a fluoride rather than a bromide as the leaving group. Here are two reactions that work well in a preparative sense with other anion-stabilizing groups. Note that the trifluoromethyl group works by using only its powerful inductive effect.

---

**To summarize**

An anion-stabilizing (electron-withdrawing) group *ortho* or *para* to a potential leaving group can be used to facilitate nucleophilic aromatic substitution.

---

**Conjugate and nucleophilic aromatic substitution reactions in action: the synthesis of an antibiotic**

We want to convince you that this chemistry is useful and also that it works in more complicated molecules so we are going to describe in part the preparation of the antibiotic ofloxacin. The sequence starts with an aromatic compound having four fluorine atoms. Three are replaced sequentially by nucleophiles and the last is present in the antibiotic itself.

The first reaction is a conjugate substitution of the ethoxy group marked in orange. An amino alcohol is used as the nucleophile and it is the more nucleophilic amino group (rather than the hydroxyl group) that adds to the alkene.

Now for the first nucleophilic aromatic substitution. The amino group attacks in the position *ortho* to the carbonyl group so that an enolate intermediate can be formed. The first fluoride is expelled in the elimination step.
Treatment with base (NaH can be used) now converts the OH group into an alkoxide, which takes part in the next aromatic nucleophilic substitution. In this reaction we are attacking the position meta to the ketone so we cannot put the negative charge on the oxygen atom. The combined inductive effect of the remaining three fluorines is enough to stabilize the anion.

Only two fluorines are left, and one of these is now displaced by an external nucleophile—an amine. The site of attack of the amine is determined by the need to stabilize the charge in the intermediate, which is an enolate.

All that is left is to hydrolyse the ester to the free acid with aqueous base (Chapter 10). Every single reaction in this quite complicated sequence is one that you have met earlier in the book, and it illustrates the power of simple organic mechanisms to allow chemists to make important life-saving compounds.

Nucleophilic substitution on aromatic rings is possible by alternative mechanisms as well. We will now turn to these.

The $S_{N}1$ mechanism for nucleophilic aromatic substitution: diazonium compounds

If we really want to make aromatic compounds undergo nucleophilic substitution in a general way, the way to do it is to use absolutely the best leaving group of all—nitrogen gas. In fact, the diazonium compound below is so good at nucleophilic aromatic substitution that is does so even without activating groups. On warming, the nitrogen molecule just departs, leaving behind a cation, which is captured by a nucleophile, in this case water. Do you find this reminiscent of the $S_{N}1$ reaction? We hope so.
Before we talk about this group of aromatic S_{\text{n}1} reactions in more detail, let’s consider how to make the diazonium salt. The reagent we need is the reactive nitrogen electrophile \( \text{NO}^+ \). You met \( \text{NO}^+ \) in Chapter 20, but to remind you, it forms when the nitrite anion (usually sodium nitrite) is treated with acid at around 0 °C. Protonation of nitrite gives nitrous acid, HONO; protonation again gives a cation, which can lose water to form \( \text{NO}^+ \). Butyl nitrite (or other alkyl nitrites) can also be used as a source of \( \text{NO}^+ \).

\[
\begin{align*}
\text{sodium nitrite} & \quad \text{H}^+ \\
\text{add HCl, 0 °C} & \quad \text{nitrous acid} \\
\text{BuO}^+ \text{N}^+ \text{O} & \quad \text{butyl nitrite}
\end{align*}
\]

A diazonium salt is formed when \( \text{NO}^+ \) reacts with an amine. The lone pair of the amine attacks the \( \text{NO}^+ \) cation, and then water is lost. The mechanism is actually quite simple, but it does involve a lot of proton transfers. There is, of course, an anion associated with the nitrogen cation, and this will be the conjugate base (Cl⁻ usually) of the acid used to form \( \text{NO}^+ \). This reaction is known as diazotization.

If the amine is an alkyl amine, this diazonium salt is very unstable and immediately loses nitrogen gas to give a planar carbocation, which normally reacts with a nucleophile in an S_{\text{n}1} process (Chapter 15), loses a proton in an E1 process (Chapter 17), or rearranges (Chapter 36). It may, for example, react with water to give an alcohol:

\[
\begin{align*}
\text{RNH}_2 & \quad \text{N} \quad \text{H} \\
\text{N} \quad \text{N} \quad \text{H} & \quad \text{H} \\
\text{OH} & \quad \text{R} \quad \text{OH}
\end{align*}
\]

If the amine is an aryl amine, then the reaction you saw at the beginning of this section will take place and a phenol will form. This is in fact rather a useful reaction as it is difficult to add an oxygen atom to a benzene ring by normal electrophilic substitution: there is no good reagent for \( \text{OH}^- \). A nitrogen atom can be added easily by nitration, and reduction and diazotization provide a way of replacing the nitro group by a hydroxyl group.

\[
\begin{align*}
\text{R} & \quad \text{NO}_2 \\
\text{Pd/C} & \quad \text{NaNO}_2, \text{HCl} \\
\text{H}_2 \text{O}, 5 °C \text{ heat} & \quad \text{R} \quad \text{OH}
\end{align*}
\]

We alluded to this sequence at the end of Chapter 21.

**Substitution reactions in the synthesis of a drug**

The synthesis of the drug thymoxamine (Moxsylyte) provides a practical example of how this reaction can be used.
It seems obvious to make this compound by alkylation and acylation of a dihydroxybenzene, but how are we to make sure that the acylation and alkylation go on the right OH groups? French pharmaceutical chemists had an ingenious answer: start with a compound having only one OH group, alkylate that, and only then introduce the second using the diazonium salt method. They used a simple phenol and introduced nitrogen as a nitroso (NO) rather than a nitro (NO₂) group. This means using the same reagent as we have been using for diazotization. These were the first two steps.

The reduction of NO is easier than that of NO₂, and H₂S is enough to do the job. The amine can now be converted to an amide to lessen its nucleophilicity so that alkylation of the phenol occurs cleanly—a form of protection (see Chapter 23).

Finally, the amide must be hydrolysed, the amino converted into an OH group by diazotization and hydrolysis, and the new phenol acetylated.

However, an aryl carbocation is much less stable than an alkyl carbocation because its empty orbital is an sp² rather than a p orbital. This makes the loss of nitrogen slower. If the diazotization is done at temperatures around 0°C (classically at 5°C), the diazonium salt is stable and can be reacted with various nucleophiles other than water.

Other nucleophiles

Aryl iodides are not as easy to make by electrophilic substitution as aryl chlorides or bromides because iodine is not reactive enough to attack benzene rings. But adding potassium iodide to the diazonium salt gives an aryl iodide by nucleophilic aromatic substitution.

Other nucleophiles, such as chloride, bromide, and cyanide, are best added as copper(I) salts. Since aromatic amines are usually made by reduction of nitro compounds, a common sequence of reactions goes like this:
As often in aromatic chemistry, it's the versatility of the nitro group that makes this sequence work—easy introduction by electrophilic substitution, easy reduction, and easy nucleophilic substitution of its diazonium derivative.

**The benzyne mechanism**

We now need to introduce you to one last mechanism for aromatic nucleophilic substitution and you may well feel that this is the weirdest mechanism you have yet seen with the most unlikely intermediate ever! For our part, we hope to convince you that this mechanism is not only possible but also useful.

Earlier in this chapter we said that the displacement by nucleophiles of bromide from bromobenzene does not occur. In fact substitution reactions of bromobenzene can occur but only under the most vigorous conditions, such as when bromobenzene and NaOH are melted together (fused) at very high temperature. A similar reaction with the very powerful reagent NaNH₂ (which supplies NH₂⁻ ion) also happens, at a rather lower temperature.

These reactions were known for a long time before anyone saw what was happening. They do not happen by an S₈₂ mechanism, as we explained earlier, and they can't happen by the addition–elimination mechanism because there is nothing to stabilize the negative charge in the intermediate. The first clue to the true mechanism is that all the nucleophiles that react in this way are very basic. They start the reaction off by removing a proton ortho to the leaving group.

The carbanion is in an sp² orbital in the plane of the ring. Indeed, this intermediate is very similar to the aryl cation intermediate in the S₈₁ mechanism from diazonium salts. That had no electrons in the sp² orbital; the carbanion has two. Why should this proton be removed rather than any other? The bromine atom is electronegative and the C–Br bond is in the plane of the sp² orbital and removes electrons from it. The stabilization is nonetheless weak and only exceptionally strong bases will do this reaction.

The next step is the loss of bromide ion in an elimination reaction. This is the step that is difficult to believe as the intermediate we are proposing looks impossible. The orbitals are bad for the elimination too—it is a syn- rather than an anti-periplanar elimination. But it happens.

The intermediate is called benzyne as it is an alkyne with a triple bond in a benzene ring. But what does this triple bond mean? It certainly isn't a normal alkyne as these are linear. In fact one π bond is normal—it is just part of the aromatic system. One π bond—the new one—is abnormal and is formed by overlap of two sp² orbitals outside the ring. This external π bond
is very weak and benzyne is a very unstable intermediate. Indeed, when the structure was proposed few chemists believed it and some pretty solid evidence was needed before they did. We shall come to that shortly, but let us first finish the mechanism. Unlike normal alkynes, benzyne is electrophilic as the weak third bond can be attacked by nucleophiles.

The whole mechanism from bromobenzene to aniline involves an elimination to give benzyne followed by an addition of the nucleophile to the triple bond of benzyne. In many ways, this mechanism is the reverse of the normal addition–elimination mechanism for nucleophilic aromatic substitution and it is sometimes called the elimination–addition mechanism.

Any nucleophile basic enough to remove the ortho proton can carry out this reaction. Known examples include oxyanions, amide anions (R₂N⁻), and carbanions. The rather basic alkoxide t-butoxide will do the reaction on bromobenzene if the potassium salt is used in the dipolar aprotic solvent DMSO to maximize reactivity. One rather special feature of the benzyne mechanism allows us to be certain that this proposed mechanism is correct, and this is the fact that the triple bond could in principle be attacked by nucleophiles at either end. This is of no consequence with bromobenzene as the products would be the same, but we can make the ends of the triple bond different and then we see something interesting. ortho-Chloro aryl ethers are easy to prepare by chlorination of the ether (Chapter 21). When these compounds are treated with NaNH₂ in liquid ammonia, a single amine is formed in good yield.

The new amino group finds itself in the meta position even though the chlorine was at the ortho position. It would be very difficult to explain this other than by the benzyne mechanism. Using the same elimination–addition sequence, this must be the mechanism:

That shows how the meta product might be formed, but why should it be formed? Attack could also occur at the ortho position, so why is there no ortho product? There are two reasons: electronic and steric. Electronically, the anion next to the electronegative oxygen atom is preferred because oxygen is inductively electron-withdrawing. The same factor facilitates deprotonation next to Cl in the formation of the benzyne. Sterically, it is better for the amide anion to attack away from the OMe group rather than come in alongside it. Nucleophilic attack on a benzyne has to occur in the plane of the benzene ring because that is where the orbitals are. This reaction is therefore very sensitive to steric hindrance as the nucleophile must attack in the plane of the substituent as well.
This is a useful way to make amino ethers with a meta relationship as both groups are ortho, para-directing and so the meta compounds cannot be made by electrophilic substitution. 

Para-Disubstituted halides can again give only one benzyne and most of them give mixtures of products. A simple alkyl substituent is too far from the triple bond to have much steric effect.

If the substituent is an electron-repelling anion, then the meta product is formed exclusively because this puts the product anion as far as possible from the anion already there. This again is useful as it creates a meta relationship between two ortho, para-directing groups.

Other evidence for benzyne as an intermediate

As you would expect, the formation of benzyne is the slow step in the reaction so there is no hope of isolating benzyne from the reaction mixture or even of detecting it spectroscopically. However, it can be made by other reactions where there are no nucleophiles to capture it, for example from this diazotization reaction.

This diazotization is particularly efficient as you can see by the quantitative yield of 2-iodobenzoic acid on capture of the diazonium salt with iodide ion. However, if the same diazonium salt is neutralized with NaOH, it gives a zwitterion with the negative charge on the carboxylate balancing the positive charge on the diazonium group. This diazotization is done with an alkyl nitrite in an organic solvent to avoid the chance that nucleophiles such as chloride or water might capture the product. When the zwitterion is heated it decomposes in an entropically favourable reaction to give carbon dioxide, nitrogen, and benzyne.

You can’t isolate the benzyne because it reacts with itself to give a benzyne dimer having a four-membered ring between two benzene rings. If the zwitterion is injected into a mass spectrometer, there is a peak at 152 for the dimer but also a strong peak at 76, which is benzyne itself. The lifetime of a particle in the mass spectrometer is about $2 \times 10^{-8}$ s so benzyne can exist for at least that long in the gas phase.
To conclude...

Alkenes and arenes are usually nucleophiles. This chapter is about the occasions on which they are not, and instead react as electrophiles. Remember that, important though the reactions in this chapter are, the principal reactivity you can expect from these compound classes is nucleophilicity.

The table below summarizes these reactions and also other similar ones you will find elsewhere in the book.

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Selectivity

Most organic molecules contain more than one functional group, and most functional groups can react in more than one way, so organic chemists often have to predict which functional group will react, where it will react, and how it will react. These questions are what we call selectivity.

Selectivity comes in three sorts: chemoselectivity, regioselectivity, and stereoselectivity. Chemoselectivity is which group reacts; regioselectivity is where it reacts. Stereoselectivity is how the group reacts with regard to the stereochemistry of the product.

- **Selectivity**

  There are three main types of selectivity:
  - chemoselectivity: which functional group will react (this chapter)
  - regioselectivity: where it will react (Chapter 24)
  - stereoselectivity: how it will react (stereochemistry of the products) (Chapters 32, 33, and 41)

We have talked a lot about regioselectivity, without calling it that, in the last two chapters. In Chapter 21 you learned how to predict and explain which product(s) you get from electrophilic aromatic substitution reactions. The functional group is the aromatic ring: where it reacts is the reaction’s regioselectivity. In Chapter 22 you saw that nucleophilic addition to an unsaturated ketone can take place in a 1,2- or 1,4-fashion—the question of which happens (where the unsaturated ketone reacts) is a question of regioselectivity. We will address regioselectivity in much more detail in the next chapter.
But this chapter is about chemoselectivity—in a compound with more than one functional group, which group reacts? Let’s start with a straightforward example—the synthesis of the painkiller paracetamol. 4-Aminophenol could react with acetic anhydride at both nitrogen and oxygen to give a compound containing an amide and an ester functional group. This is what happens on heating with excess acetic anhydride (Ac₂O) in toluene.

But with just one equivalent of acetic anhydride in the presence of a base (pyridine) only the NH₂ group is acylated, and paracetamol is the product. This is chemoselectivity, and it is to be expected that the NH₂ group is more nucleophilic than the OH group. It is even possible to hydrolyse the doubly acetylated product to paracetamol with aqueous sodium hydroxide. The ester is more reactive than the amide and hydrolyses much more easily. This is another chemoselective reaction.

We know that ketones are more reactive towards Grignard reagents and organolithiums than esters because you can’t isolate a ketone from the reaction of an ester with a Grignard reagent or an organolithium. Chemists at the pharmaceutical company Pfizer made use of this fact while they were developing anticonvulsants related to the tranquillizer oblivon. By adding lithium acetylide to ketones, they were able to make a tertiary alcohol by chemoselective reaction of a ketone in the presence of an ester.

These last two reactions work because, although each starting material contains two carbonyl groups, one is more electrophilic and therefore more reactive towards nucleophiles (OH⁻ in the first case; lithium acetylide in the second) than the other. We can order carbonyl compounds into a sequence in which it will usually be possible to react those on the left with nucleophiles in the presence of those on the right.
We’ve already discussed this sequence of reactivity in relation to acid derivatives in Chapter 10—make sure you understand the reason for the ordering of ester > amide > carboxylate. Here we’re adding to the list aldehyde (the most reactive, for steric reasons—it is the least hindered) and ketone (more reactive than esters because the carbonyl group is not stabilized by conjugation with a lone pair).

Reducing agents

Chemists at Glaxo exploited this reactivity sequence in their synthesis of the anti-asthma drug salmefamol (sister compound to the bestseller salbutamol). Three reducing agents are used in the sequence: sodium borohydride (NaBH₄), hydrogen gas over a palladium catalyst, and lithium aluminium hydride (LiAlH₄).

Why not use LiAlH₄ all the time?

In general, it’s best to use the mildest conditions possible for any particular reaction—the potential for unwanted side-reactions is lessened. What is more, NaBH₄ is a lot easier to handle than LiAlH₄—for example, it simply dissolves in water while LiAlH₄ catches fire if it gets wet. NaBH₄ is usually used to reduce aldehydes and ketones, even though LiAlH₄ also works.

We shall use this synthesis as a basis for discussion on chemoselectivity in reductions. In the first step, sodium borohydride leaves the carbonyl group of the ester untouched while it reduces the ketone (in orange); in the last step, lithium aluminium hydride reduces the ester (in black). These chemoselectivities are typical of these two most commonly used reducing agents: borohydride can usually be relied upon to reduce an aldehyde or a ketone in the presence of an ester, while lithium aluminium hydride will reduce almost any carbonyl group.

Reduction of carbonyl groups

We should now look in detail at reductions of carbonyl compounds, and in doing so we shall introduce a few more specialized reducing agents. Then we will come back to the other type of reduction in the salmefamol synthesis—catalytic hydrogenation.

How to reduce aldehydes and ketones to alcohols

We don’t need to spend much time on this—sodium borohydride, which you met in Chapter 6, does it very well. Sodium borohydride will reduce only in protic solvents (usually ethanol or methanol) or in the presence of electrophilic metal cations such as Li⁺ or Mg²⁺ (LiBH₄ can be used in THF, for example). The mechanism follows a course which can be represented like this.

The essence of the reaction is the transfer of a hydrogen atom with two electrons (called hydride transfer, although no hydride ion is involved) from boron to carbon. The developing
negative charge on oxygen is protonated by the alcohol, and resulting alkoxide adds to the boron during or immediately after the reduction. The by-product, an alkoxyborohydride anion, is itself a reducing agent, and can go on to reduce three more molecules of carbonyl compound, transferring step-by-step all of its hydrogen atoms.

**How to reduce esters to alcohols**

LiAlH$_4$ is often the best reagent, and gives alcohols by the mechanism we discussed in Chapter 10 (p. 217). As a milder alternative (needed because LiAlH$_4$ has caused countless fires through careless handling), lithium borohydride in alcoholic solution will reduce esters—in fact, it has useful selectivity for esters over acids or amides that LiAlH$_4$ does not have. Sodium borohydride reduces most esters only very slowly.

**How to reduce amides to amines**

Again, LiAlH$_4$ is a good reagent for this transformation. The mechanism follows a similar course to the reduction of esters: both are written out in detail below, and there is a key difference at the steps boxed in orange and in green. In the orange box, loss of alkoxide from the tetrahedral intermediate forms an aldehyde, which is reduced further. This doesn’t happen with amides; instead the anionic oxygen is lost—assisted by coordination to aluminium—to form an iminium ion. A good alternative for the reduction of amides to amines is borane (BH$_3$), described in the next section.

**LiAlH$_4$ reduction of esters**

**LiAlH$_4$ reduction of amides**

**How to reduce carboxylic acids to alcohols**

The best reagent for this is borane, BH$_3$. Borane is, in fact, a gas with the structure B$_2$H$_6$, but it can be ‘tamed’ as a liquid by complexing it with ether (Et$_2$O), THF, or dimethyl sulphide (DMS, Me$_2$S).

Although borane appears superficially similar to borohydride, it is not charged, and that makes all the difference to its reactivity. Whereas borohydride reacts best with the most electrophilic carbonyl groups, borane’s reactivity is dominated by its desire to accept an electron pair into the boron’s empty p orbital. In the context of carbonyl group reductions, this means that borane reduces electron-rich carbonyl groups fastest. The carbonyl groups of
ACYL CHLORIDES AND ESTERS ARE RELATIVELY ELECTRON-POOR (Cl AND OR ARE VERY ELECTRONEGATIVE); BORANE WILL NOT TOUCH ACYL CHLORIDES AND REDUCES ESTERS ONLY SLOWLY. BUT IT WILL REDUCE VERY EFFECTIVELY BOTH CARBOXYLIC ACIDS AND AMIDES.

BORANE REACTS WITH CARBOXYLIC ACIDS FIRST OF ALL TO FORM TRIACYLBORATES, WITH EVOLUTION OF HYDROGEN GAS. ESTERS ARE USUALLY LESS ELECTROPHILIC THAN KETONES BECAUSE OF CONJUGATION BETWEEN THE CARBONYL GROUP AND THE LONE PAIR OF THE SP³ HYBRIDIZED OXYGEN ATOM—but, IN THESE BORON ESTERS, THE OXYGEN NEXT TO THE BORON HAS TO SHARE ITS LONE PAIR BETWEEN THE CARBONYL GROUP AND THE BORON’S EMPTY P ORBITAL, SO THEY ARE CONSIDERABLY MORE REACTIVE THAN NORMAL ESTERS.

\[
\begin{align*}
\text{R} & \quad \text{O} \quad \text{B} \quad \text{R} \quad \text{O} \quad \text{BH}_3 \\
\text{O} \quad \text{OH} & \quad \xrightarrow{\text{BH}_3} \quad \text{O} \quad \text{B} \quad 3 \\
& \quad \text{fast} + 3 \times \text{H}_2
\end{align*}
\]

BORANE IS A HIGHLY CHEMOSELECTIVE REAGENT FOR THE REDUCTION OF CARBOXYLIC ACIDS IN THE PRESENCE OF OTHER REDUCIBLE FUNCTIONAL GROUPS SUCH AS ESTERS, AND EVEN KETONES.

BORANE AND LITHIUM BOROHYDRIDE ARE A MOST USEFUL PAIR OF REDUCING AGENTS, WITH OPPOSITE SELECTIVITIES. JAPANESE CHEMISTS USED AN ENZYME TO MAKE A SINGLE ENANTIOMER OF THE ACID BELOW, AND WERE ABLE TO REDUCE EITHER THE ESTER OR THE CARBOXYLIC ACID BY CHOOSING LITHIUM BOROHYDRIDE OR BORANE AS THEIR REAGENT. CHECK FOR YOURSELF THAT THE LACTONES (CYCLIC ESTERS) IN BLACK FRAMES ARE ENANTIOMERS.

Because borane reacts well with electron-rich carbonyl groups, it is also a good alternative to LiAlH₄ for reducing amides to amines, and is chemoselective even in the presence of an ester:

\[
\begin{align*}
\text{N} & \quad \text{O} \quad \text{Ph} \\
\text{O} \quad \text{H}_2 \quad \text{N} & \quad \text{O} \quad \text{Me} \\
\text{Me} & \quad \text{Me}
\end{align*}
\]

The carbonyl group of an amide is electron-rich because it receives electron density from the delocalized N lone pair. It therefore complexes well with the empty p orbital of the Lewis acidic borane. Hydride transfer is then possible from anionic boron to electrophilic carbon. The resulting tetrahedral intermediate collapses to an iminium ion that is reduced again by the borane.
**How to reduce esters or amides to aldehydes**

The step boxed in orange in the ester reduction scheme on p. 531 gave an aldehyde. The aldehyde is more readily reduced than the ester, so the reduction doesn’t stop there, but carries on to the alcohol oxidation level. How, then, can you reduce an ester to an aldehyde? This is a real problem in synthetic chemistry—the ester below, for example, is easy to make by methods you will meet in Chapter 25, but an important synthesis of the antibiotic monensin requires the aldehyde.

![Reduction of Carbynol Groups](image)

In this case, the chemists decided simply to put up with the fact that LiAlH₄ gives the alcohol, and oxidize the alcohol back to the aldehyde using chromium(VI), the oxidant you met in Chapter 9 (p. 194). There is, however, a reagent that will sometimes do the job in a single step, although you must bear in mind that this is not at all a general reaction. The reagent is known as DIBAL or DIBALH—diisobutyl aluminium hydride, i-Bu₂AlH.

DIBAL is an alane: its structure is shown in the margin. Its chemistry is in many ways like borane—it exists as a bridged dimer, and it becomes a reducing agent only after it has formed a Lewis acid–base complex, so like borane it too reduces electron-rich carbonyl groups most rapidly. DIBAL will reduce esters even at –70 °C, and at this temperature the tetrahedral intermediate, formed by the transfer of hydride from aluminium to carbon (and shown below), may be stable. Only in the aqueous work-up does it collapse to the aldehyde. This step also destroys any excess DIBAL so no further reduction is possible.

![Reduction of Carbynol Groups](image)

**Lactols from lactones**

A stable tetrahedral intermediate is more likely in the reduction of lactones, for the same reasons that cyclic hemiacetals are more stable than acyclic ones. DIBAL is most reliable in the reduction of lactones to cyclic hemiacetals (also known as lactols), as in this reaction from E. J. Corey’s synthesis of the prostaglandins.
In the amide reduction scheme on p. 533, the step framed in green gives an iminium ion. Stopping the reaction before the iminium ion forms would therefore provide a way of making aldehydes from amides because in the absence of the aluminium, this tetrahedral intermediate collapses to an aldehyde. Because tetrahedral intermediates like these formed during amide reduction are rather more stable than those from ester reduction, this can often be achieved simply by carrying out the amide reduction and quenching with water, all at 0 °C.

DIBAL is also good for reducing nitriles to aldehydes. Indeed, this reaction and the reduction of lactones to lactols (see box above) are the best things that DIBAL does.

The box below summarizes the chemoselectivity of all of these reagents.

**Hydrogen as a reducing agent: catalytic hydrogenation**

The simplest reducing agent is hydrogen itself, H₂. Hydrogen can’t generally be used as a reducing agent for carbonyl compounds—it isn’t nucleophilic enough. However, it can act as
a reducing agent for other, weaker, double and triple bonds, such as C=–C, C=–N, C≡–C and C≡–N. To do these reactions, a metal catalyst is required and the process is known as catalytic hydrogenation. The hydrogen is provided by a cylinder, perhaps via a balloon, or can be made by electrolysis and pumped with the substrate over the catalyst. In the example below, the alkene is reduced while the aldehyde remains untouched.

The catalysts used to make hydrogen react with double bonds are transition metals: usually palladium (as in this example) or platinum, but sometimes nickel, rhodium, or ruthenium. We will talk about several different reductions in this section, but the mechanisms of all of them are similar, and very different from those involved in carbonyl reductions.

Catalytic hydrogenation takes place on the surface of the metal. The metal must therefore be finely divided, and is usually dispersed on the surface of an inert support. This is what ‘Pd/C’ means—finely divided palladium carried on a charcoal support. The first step is chemical absorption of hydrogen onto the metal surface, a process that results in breakage of the H–H bonds and distributes hydrogen atoms where they can react with the organic substrate. Now the alkene can also bond to the metal, and hydrogen can be transferred from the metal to the alkene.

How to reduce alkenes to alkanes

Hydrogenation with a palladium or a platinum catalyst is the most common way of reducing alkenes. You may find our mechanism rather unsatisfactory, but it is hard to draw curly arrows for the reactions involved here. There is, however, plenty of evidence that the hydrogenation occurs like this, for example the alkene below reacts in such a way that the major product receives both hydrogen atoms on the same face of the molecule—just what we would expect from a reaction at a surface.
**Hydrogenated vegetable oil**

Plants such as soya, rapeseed, cottonseed, and sunflower are useful sources of edible vegetable oils, but these oils are unsuitable as butter substitutes because of their low melting points. Their low melting points relative to animal fats are largely due to cis double bonds that disrupt the packing of the alkyl chains in the solid state. Treating the crude vegetable oil with hydrogen over a metal catalyst removes some of these double bonds, increases the proportion of saturated fat in the oil, and raises its melting point, making it suitable for making margarine.

![melting points of some common fatty acids](image)

The reaction is usually stopped before all the double bonds are hydrogenated, of course: margarine manufacturers are desperate to tell us that their products are still ‘high in unsaturated fatty acids’. Many also advertise that they are ‘low in trans unsaturated fatty acids’ because of a suggested link between incidence of coronary heart disease and trans unsaturated fatty acid intake.

Where have these trans double bonds come from? Well, partial hydrogenation can lead to significant double-bond isomerization, not just to regioisomers but to geometrical isomers too.

**How to reduce α,β-unsaturated carbonyl compounds**

It should not now surprise you that regioselective reduction of the C=C double bond of an α,β-unsaturated carbonyl compound is best done using catalytic hydrogenation as the C=C bond is more susceptible to hydrogenation than the C=O bond. The flavouring compound known as raspberry ketone is made by this method.

![raspberry ketone](image)

But what if you want instead to reduce the C=O group selectively? You should immediately think of using NaBH₄. But in Chapter 22 we pointed out that hydride reducing agents in general are not good choices for the selective reduction of the C=O bond of unsaturated carbonyl compounds because they tend to add to the double bond as well, giving first the saturated carbonyl compound, which is then reduced to the alcohol. The way to get regioselective addition directly to the carbonyl group is to use NaBH₄ in the presence of a hard, Lewis-acidic metal salt, such as CeCl₃. This combination of reagents is known as the Luche reduction.

See Chapter 22 for a discussion of the reactivity of α,β-unsaturated carbonyl compounds.
How to reduce benzene rings to cyclohexanes

Even aromatic rings can be hydrogenated in preference to C=O groups: in these examples the ester and acid survive while phenyl is reduced to a cyclohexyl group.

\[
\text{NaBH}_4 + \text{CeCl}_3 \rightarrow \text{NaBH}_4 \rightarrow \text{alkene} \rightarrow \text{alkane}
\]

The catalyst used in each reduction can be a matter of trial and error, and it is difficult to predict which metal will be most successful—generally Pt, Rh, or Ni is used for arenes.

How to reduce alkynes to alkenes

A catalyst known as Lindlar’s catalyst (which you will meet again in Chapter 27) is used to reduce alkynes to alkenes, but does not easily reduce alkenes to alkanes. This requires rather subtle chemoselectivity: alkynes are usually hydrogenated at least as fast as alkynes, so we need to be sure the reaction stops once the alkene has been formed. The Lindlar catalyst is a palladium catalyst (Pd/\text{CaCO}_3) deliberately poisoned with lead. The lead lessens the activity of the catalyst and makes further reduction of the alkene product slow: most palladium catalysts would reduce alkynes all the way to alkanes. Best selectivities are obtained if quinoline is also added to the reaction, and alkyne to alkene reductions work with Pd/\text{BaSO}_4 + quinoline too. Even so, Lindlar reactions often have to be monitored carefully to make sure that over-reduction is not taking place.

How to reduce acid chlorides to aldehydes

Catalytic hydrogenation is often chosen as a method for reduction because of its chemoselectivity for C=C over C=O groups, and an important hydrogenation involving a carbonyl compound is not actually a reduction of the C=O double bond. Hydrogenation of acyl chlorides gives aldehydes in a reaction known as the Rosenmund reaction—really a hydrogenolysis of a C–Cl bond.

\[
\text{acyl chloride} + \text{H}_2 + \text{BaSO}_4 \rightarrow \text{aldehyde}
\]

This is a good way of reducing compounds at the carboxylic acid oxidation level to aldehydes, which is why we included it in the table of carbonyl reductions on p. 534.
The quinoline is needed both to neutralize the HCl produced in the reaction and to moderate the activity of the catalyst, preventing over-reduction.

**Reductive amination by catalytic hydrogenation**

The unreactivity of carbonyl groups towards catalytic hydrogenation allows us to use hydrogenation in a similar way to sodium cyanoborohydride to carry out reductive aminations of amines and carbonyl compounds. For example, in the synthesis of salmefamol we presented on p. 530, one step involves the formation of the imine from an amine and a ketone in the presence of acid, hydrogen, and a palladium catalyst. The imine (in its protonated iminium form) is hydrogenated to yield an amine, while the ketone (and the aromatic systems) remains untouched.

![Imine formation and hydrogenation](image)

**How to reduce nitro groups to amines**

In Chapters 21 and 22 we saw how the sequence of nitration of aromatic rings followed by reduction was a useful route to aromatic amines. The reduction of the nitro group can be carried out by Sn/HCl but catalytic hydrogenation is much simpler. The reaction is usually done in ethanol with a Pd or Pt catalyst, and it may be necessary to add a weak acid to prevent the amine produced from poisoning the catalyst. The real gain over the Sn/HCl method is in the work-up. Instead of separating and disposing of voluminous toxic tin residues, a simple filtration to remove the catalyst, evaporation, and crystallization or distillation gives the amine.

![Nitro reduction](image)

**Hydrogenolysis: breaking C–O and C–N bonds**

In the reductive amination above we skirted over the fact that the starting amine in the synthesis of salmefamol (look back at p. 530) in fact carries two benzyl groups, which disappear during the hydrogenation.

![Hydrogenolysis](image)

What happens to them is a hydrogenolysis—a reaction that is liable to occur under catalytic hydrogenation conditions whenever a heteroatom (in particular O or N) finds itself bonded to a carbon atom adjacent to a benzene ring, in other words with benzylic amines, alcohols or ethers.
Hydrogenolysis happens under similar conditions to alkene hydrogenation, but involves breakage of a C–O or C–N bond rather than a C=C π bond. It is particularly important for removing benzyl protecting groups, to which we will return later in the chapter.

- We can draw up a sequence of reactivity towards hydrogenation. The precise ordering varies with the catalyst, and some catalysts are particularly selective towards certain classes of compound—for example, Pt, Rh, and Ru will selectively hydrogenate aromatic rings in the presence of benzyl C–O bonds, while with Pd catalysts the benzyl C–O bonds are reduced faster.

**Getting rid of functional groups**

Functional groups can be useful for putting a molecule together, but they aren’t always needed in the final product. We need ways of getting rid of them. Hydrogenation of alkenes is one way that you have seen. Hydrogenation of alkynes to alkanes is very useful because we can build long chains of carbon atoms by alkylating alkynes, then hide the evidence by hydrogenation:

Alcohols can be got rid of either by elimination to alkenes and then hydrogenation or by tosylation and substitution using borohydride to provide a nucleophilic hydrogen atom.
Removal of carbonyl groups is harder, although there are several possible methods. C–O bonds are strong, but C–S bonds are much weaker and are often easily reduced with Raney nickel. We can get rid of aldehyde and ketone carbonyl groups by making them into thiaoacetals, sulfur analogues of acetals, formed in a reaction analogous to acetal formation (see Chapter 11) but using a dithiol with a Lewis acid catalyst. Freshly prepared Raney nickel carries enough H₂ (p. 537) to reduce the thioacetal without added hydrogen.

A slightly more vigorous method, known as the Wolff–Kishner reduction, is driven by the elimination of nitrogen gas from a hydrazone. Hot concentrated sodium hydroxide solution deprotonates the hydrazone, which can then lose nitrogen to form an alkyl anion, which is immediately protonated by water.

The third method is the simplest to do, but has the most complicated mechanism. The Clemmensen reduction is also rather violent, and really reasonable only for compounds with just the one functional group. It uses zinc metal dissolving in concentrated hydrochloric acid. As the metal dissolves, it gives up two electrons—in the absence of something else to do, these electrons would reduce the H⁺ in the acid to H₂, and give ZnCl₂ and H₂. But in the presence of a carbonyl compound, the electrons go to reduce the C=O bond.

The mechanism has a good deal in common with a whole class of reductions, of which the Clemmensen is a member, known as dissolving metal reductions. We shall now look at these as our third (after metal hydrides and catalytic hydrogenation) important class of reducing agents.

Two synthetic routes to muscalure—the house fly pheromone

Many insects attract a mate by releasing a volatile organic compound known as a pheromone. Pheromones are highly specific to species and provide a cunning means of controlling pests: place a pad of cotton wool soaked in male pheromone inside a trap and in drop all the female pests—no next generation. If insect control is to rely on a supply of the pheromone, that supply has to be synthetic—it takes enormous numbers of squashed insects to provide even a few milligrams of most pheromones.

Two syntheses of the very simple pheromone of a very common insect—the house fly—provide an illustration of how to use two of the reduction methods we have just described. The pheromone, known as muscalure, is a Z-alkene.
One approach, used by some American chemists in the early 1970s, was very simple. These chemists noted the similarity between the structures of muscalure and the fatty acid known as erucic acid, which is abundant in rapeseed oil, and decided to make muscalure from erucic acid. They first reacted the acid with two equivalents of methyllithium—the first equivalent deprotonates the acid to make a lithium carboxylate salt, while the second reacts with the lithium carboxylate to make a ketone (see p. 219).

\[
\text{erucic acid, a fatty acid extracted from rapeseed oil}
\]

The next step is to remove the ketone functional group. The method chosen was the Wolff–Kishner reaction described on p. 540: make a hydrazone and heat in the presence of base. Muscalure is the product.

Later some Russian chemists made the same compound by a different route. They chose to introduce the Z double bond by hydrogenation of an alkyne over Lindlar’s catalyst (p. 537). To make the alkyne they needed, they took 1-decyne, treated it with LiNH₂ to remove the acidic terminal proton, and reacted the anion with an n-alkyl bromide. By stirring the alkyne with Lindlar’s catalyst under an atmosphere of hydrogen they were able to make muscalure.

**Dissolving metal reductions**

You will be familiar with the idea that many metals react with acid to liberate hydrogen, forming a salt at the same time. There is an example in the margin. The metal cation (Mg²⁺ in this example) results from the loss of electrons, and these electrons reduce \(2 \times \text{H}^+\) to give \(\text{H}_2\).

The same thing happens even in very weak acids (water, alcohols…even liquid ammonia) if the metal is very reactive (sodium or potassium, say). You can think of the process here in two steps: first sodium releases an electron, then the electron is captured by a proton from NH₃ to give H, which forms H₂. Sodium ethoxide (NaOEt) and sodium amide (NaNH₂, p. 171) are made by dissolving sodium in ethanol or liquid ammonia, respectively.

But what if, instead of just reducing the solvent to liberate hydrogen, we harness the electrons by giving them a more easily reduced substrate instead? A dissolving metal reduction results: note dissolving. The electrons have to be captured as the metal releases them, otherwise they will just reduce the solvent to give \(\text{H}_2\).
Dissolving metal reductions work because the electrons released as reactive metals form soluble cations that can be harnessed to do other, more useful, reductions. Electrons are the simplest possible reducing agents, and they will reduce carbonyl compounds, alkynes, or aromatic rings—in fact any functional group with a low-energy $\pi$ orbital into which the electron can go.

**Birch reduction of arenes**

We shall start by looking at the dissolving metal reduction of aromatic rings, known as the **Birch reduction**. The margin shows the reaction of benzene with lithium in liquid ammonia. At first sight this reaction looks improbable, with an aromatic ring ending up as an unconjugated diene. The mechanism will explain why we get this regiochemistry, and also why the reaction stops there—in other words, why the dissolving lithium reduces an aromatic ring more readily than an alkene.

The first thing to note is that when lithium or sodium dissolve in ammonia they give an intense blue solution. Blue is the colour of solvated electrons: these group 1 metals ionize to give Li$^+$ or Na$^+$ and e$^-$($\text{NH}_3$)$_n$. With time, the blue colour fades, as the electrons reduce the ammonia to $\text{NH}_2^-$ and H$_2$.

Birch reductions use those blue solutions, with their solvated electrons, as reducing agents. The reduction of NH$_3$ to $\text{NH}_2^-$ and H$_2$ is quite slow, and a better electron acceptor will get reduced in preference. With benzene, the electrons go into the lowest lying antibonding orbital (benzene’s LUMO). The species we get can be represented in several ways, all of them radical anions (molecules with one excess unpaired electron). The radical anion is very basic, and it picks up a proton from the ethanol that is in the reaction mixture.

The molecule is now no longer anionic, but it is still a radical. It can pick up another electron, which pairs with the radical to give an anion, which is quenched again by the proton source (ethanol). Overall we have arrived at two additional H atoms by sequentially adding two electrons plus two protons.

More questions of regioselectivity arise when there are substituents around the aromatic ring. Here are two examples.
These examples serve to illustrate a general principle:

- Electron-withdrawing groups promote *ipsos*, *para* Birch reduction.
- Electron-donating groups promote *ortho*, *meta* Birch reduction.

The explanation must lie in the distribution of electron density in the intermediate radical anions. Electron-withdrawing groups stabilize electron density at the *ipsos* and *para* positions, and protonation occurs *para*.

![Chemical structures showing electron-withdrawing and donating groups in Birch reduction](image)

while electron-donating groups stabilize *ortho* and *meta* electron density:

![Chemical structures showing electron-withdrawing and donating groups in Birch reduction](image)

If you want the conjugated dienes as products, it is quite a simple matter to isomerize them using an acid catalyst. In fact, a small amount (about 20%) of the conjugated product is produced anyway in the reaction of anisole above. With anilines, it is impossible to stop the isomerization taking place during the reaction, and Birch reduction always gives conjugated dienamines.

![Chemical structures showing isomerization into conjugation](image)

**Birch reduction of alkynes**

Birch reduction works for alkynes too and reduces them to *trans* alkenes.

![Chemical structures showing Birch reduction of alkynes](image)

The mechanism follows the same course as the reduction of aromatic rings, but the vinyl anion is basic enough to deprotonate ammonia, so no added proton source is required. Vinyl anions are geometrically unstable, and choose to be *E*. Again, the two green H atoms come from two electrons and two protons.
Selectivity in oxidation reactions

In Chapter 9 you met some chromium-based oxidants that convert primary or secondary alcohols to aldehydes or ketones. We mentioned in that chapter the possibility, when an aldehyde is the product of the oxidation, that a further oxidation will take place to make a carboxylic acid. The problem does not arise of course when a secondary alcohol is oxidized to a ketone.

Since then you have met some other oxidizing agents too, particularly in Chapter 19:

- On p. 429 you saw peracids as oxidizing agents for \(\text{C} = \text{C}\) double bonds—they give epoxides.
- On p. 442 you saw osmium tetroxide (\(\text{OsO}_4\)) giving diols from alkenes.
- On p. 443 we introduced ozone (\(\text{O}_3\)) as a means of cleaving alkenes to carbonyl compounds by ozonolysis.

Unlike Cr(VI), none of these reagents will oxidize a hydroxyl group: they are chemoselective for \(\text{C} = \text{C}\) double bonds, but do not react with hydroxyl groups. By contrast, Cr(VI) oxidizes alcohols but not alkenes.

<table>

</tbody>
</table>

In this section we will be concerned only with oxidizing agents that oxidize alcohols and carbonyl compounds, and in particular we shall be concerned with ways of choosing whether to arrest the oxidation of primary alcohols at the aldehyde stage or let it continue to the carboxylic acid.

The most commonly used methods for oxidizing alcohols are based around metals in high oxidation states, often chromium(VI) (which you met in Chapter 9) or manganese(VII), and you will see that mechanistically they are quite similar—they both rely on the formation of a bond between the hydroxyl group and the metal. Another class of oxidations, those that use halogens, sulfur, or nitrogen in high oxidation states, we will deal with relatively briefly.

How to oxidize secondary alcohols to ketones

You met methods for this reaction in Chapter 9, where you met the use of Cr(VI) in the form of \(\text{Cr}_2\text{O}_7^{2-}\). One common version of this reaction is the Jones oxidation, shown in the margin. The mechanism starts with the formation of \(\text{HCrO}_4^-\) ions, that is, Cr(VI), from dichromate ion in solution. In acid, these Cr(VI) species form chromate esters with alcohols. Chromate esters decompose by elimination of a Cr(IV) species, which subsequently reacts with Cr(VI) to yield 2 \(\times\) Cr(V). These Cr(V) species can oxidize alcohols in the same way and are thereby reduced to Cr(III) (the final metal-containing by-product). Cr(VI) is orange and Cr(III) is green, so the progress of the reaction is easy to follow by colour change.
Chromic acid is best avoided if acid-sensitive alcohols are to be oxidized, and an alternative reagent for these is PCC (pyridinium chlorochromate), which can be used in dichloromethane.

**How to oxidize primary alcohols to aldehydes**

Aqueous methods like the Jones oxidation are no good for this, since the aldehyde that forms is further oxidized to acid via its hydrate. The oxidizing agent treats the hydrate as an alcohol, and oxidizes it to the acid.

The key thing is to avoid water, so PCC in dichloromethane works quite well. The related reagent PDC (pyridinium dichromate) is particularly suitable for oxidation to aldehydes. Some very mild oxidizing agents are being more and more widely used for the synthesis of very sensitive aldehydes. One of these is known as TPAP (tetra-n-propylammonium perruthenate, pronounced ‘tee-pap’). TPAP can be used catalytically, avoiding the large amounts of toxic heavy metal by-products generated by most chromium oxidations. The stoichiometric oxidant in this reaction is NMO (N-methylmorpholine-N-oxide), which is reduced to the amine, reoxidizing the ruthenium to Ru(VII).

Another important mild oxidant is a high-valent iodine compound known as the Dess–Martin periodinane. It can be made from 2-iodobenzoic acid.

It will oxidize even very sensitive alcohols to carbonyl compounds—few others, for example, would give the cis-α,β-unsaturated aldehyde in the margin from a cis-allylic alcohol without isomerizing it to trans, or producing other by-products. We shall leave detailed discussion of one more method till much later, in Chapter 27, since the mechanism involves some sulfur chemistry you will meet there, but we introduce it here because of its synthetic importance. Known as the Swern oxidation, it uses a sulfoxide [sulfur(IV)] as the oxidizing agent. The sulfoxide is reduced to a sulfide, while the alcohol is oxidized to an aldehyde.

---

The abbreviations THP and TBDMS will be explained later in this chapter (p. 550).

For more details, and the mechanism of the Swern oxidation, see p. 667.
How to oxidize primary alcohols or aldehydes to carboxylic acids

Sometimes the ‘over-oxidation’ we were trying to avoid in oxidizing alcohols to aldehydes is actually the reaction you want. It’s best done with an aqueous solution of Cr(VI) or Mn(VII). Acidic or basic aqueous potassium permanganate is often a good choice. From alcohols in acidic solution the mechanism follows very much the lines of the chromic acid mechanism; from aldehydes, the mechanism is very similar.

\[
\begin{align*}
R\text{O}H & \xrightarrow{\text{oxidation of aldehydes with Mn(VII)}} R\text{CHO} + \text{Mn}(V) \\

Competing reactivity: choosing which group reacts

We hope that our survey of the important methods for reduction and oxidation has shown you that, by choosing the right reagent, you can often get reaction only at the functional group you want. The chemoselectivity you obtain is kinetic chemoselectivity—reaction at one functional group is simply faster than at another.

Now look at the acylation of an amino alcohol (which is, in fact, a synthesis of the painkiller isobucaine) using benzoyl chloride under acid conditions. The hydroxyl group is acylated to form an ester. Yet under basic conditions, the selectivity is quite different, and an amide is formed.

A clue to why the selectivity reverses is shown below—it is, in fact, possible to interconvert the ester and the amide simply by treating either with acid or with base.

The selectivity in these reactions is thermodynamic chemoselectivity. Under conditions in which the ester and amide can equilibrate, the product obtained is the more stable of the two, not necessarily the one that is formed faster. In base the more stable amide predominates, while in acid the amine is protonated, which prevents it from acting as a nucleophile and removes it from the equilibrium, giving the ester.
How to react the less reactive group (I): react both then ‘unreact’ one

The relative reactivity of the alcohol and amine in the example just given could be overturned by conducting a reaction under thermodynamic control. In kinetically controlled reactions, the idea that you can conduct chemoselective reactions on the more reactive of a pair of functional groups—carbonyl-based ones, for example—is straightforward. But what if you want to react the less reactive of the pair? There are two commonly used solutions. The first is illustrated by a compound needed by chemists in Cambridge to study an epoxidation reaction. They were able to make the following diol, but wanted to acetylate only the more hindered secondary hydroxyl group.

Treatment with one equivalent of an acetylating agent is no good because the primary hydroxyl group is more reactive; instead, the chemists acetylated both hydroxyl groups, and then treated the bis-acetate with mildly basic methanol (K₂CO₃, MeOH, 20 °C), which reacted only at the less hindered acetoxy group and gave the desired compound in 65% yield.

In other words, start by letting both groups react and then go backwards so the reaction is reversed, but at only one of the two groups. Steric hindrance means that the less favourable reaction (in other words, reaction at the less reactive group) was also less readily reversed.

Chemoselectivity in the reactions of dianions

A similar idea is central to a useful bit of chemoselectivity that can be obtained in the reactions of dianions. 1-Propynol can be deprotonated twice by strong bases—first, at the hydroxyl group to make an alkoxide anion (the pKₐ of the OH group is about 16) and, secondly, at the alkyne (pKₐ of the order of 25) to make a dianion. When this dianion reacts with electrophiles it always reacts at the alkynyl anion and not at the alkoxide.

This reaction is important in a synthesis of the perfumery compound cis-jasmone. The alkyne is the precursor to cis-jasmone’s alkene side chain.

- Reactivity of dianions
  The anion that is formed last reacts first.
Vollhardt used this sort of chemoselectivity in his 1977 synthesis of the female sex hormone oestrone. He needed an alkyl iodide, which could be made by reacting an anion of a bis-alkyne with ethylene oxide.

Although anions can often be formed straightforwardly next to alkynes, there are two other more acidic protons (black) in the molecule that would be removed by base before the green proton. However, treatment with three equivalents of butyl lithium removes all three, and the trianion reacts with ethylene oxide at the last-formed anionic centre to give the required compound.

**How to react the less reactive group (II): protecting groups**

The more usual way of reacting a less reactive group in the presence of a more reactive one is to use a **protecting group**. This tertiary alcohol, for example, could be made from a keto-ester if we could get phenylmagnesium bromide to react with the ester rather than with the ketone.

As you would expect, simply adding phenylmagnesium bromide to ethyl acetoacetate leads mainly to addition to the more electrophilic ketone.

One way of making the alcohol we want is to **protect** the ketone from attack by disguising it from the nucleophile. An acetal protecting group (shown in black) is used.

The first step puts the protecting group on to the (more electrophilic) ketone carbonyl, making it no longer reactive towards nucleophilic addition. The Grignard then adds to the ester, and finally a ‘deprotection’ step, acid-catalysed hydrolysis of the acetal, gives us back the ketone. An acetal is an ideal choice here—acetals are stable to base (the conditions of the reaction we want to do), but are readily cleaved in acid.
A survey of protecting groups

A dioxolane can be used in this way to protect aldehydes and ketones from powerful, basic nucleophiles, and makes the first entry in the tour of important protecting groups we shall conduct you through in the next few pages.

By protecting sensitive functional groups like ketones it becomes possible to make reagents that would otherwise be unstable. In a synthesis of the natural product porantherine, a compound based on the structure in the margin was needed. As it’s a symmetrical secondary alcohol (see p. 216), a good way to make it is to add a Grignard reagent twice to ethyl formate.

![Grignard reagent](image)

But, of course, a ketone-containing Grignard is an impossibility as it would self-destruct, so an acetal-protected compound was used. Acid-catalysed hydrolysis of the two dioxolanes, coloured green, reveals the diketone.

![Acetal hydrolysis](image)

Strongly nucleophilic reagents like Grignard reagents and organolithiums are also strong bases and may need protecting from acidic protons as well as from electrophilic carbonyl groups. Among the most troublesome are the protons of hydroxyl groups. When some American chemists wanted to make the antiviral agent Brefeldin A, they needed the simple alkynol in the margin.

A synthesis could start with the same bromoketone as the one above: reduction gives an alcohol, but alkylation of an alkynyl anion with this compound is not possible because the anion will just deprotonate the hydroxyl group.

![Alkylation problem](image)

The answer is to protect the hydroxyl group with a group resistant to base, and the group chosen here was a silyl ether. Such ethers are made by reacting the alcohol with a trialkylsilyl chloride (here tert-butyldimethylsilyl chloride, or TBDMScI) in the presence of a weak base, usually imidazole, which also acts as a nucleophilic catalyst (Chapter 12).
Silicon has a strong affinity for electronegative elements, particularly O, F, and Cl, so trialkysilyl ethers are attacked by hydroxide ion, water, or fluoride ion but are more stable to carbon or nitrogen bases or nucleophiles. They are usually removed with aqueous acid or fluoride salts, particularly \( \text{Bu}_4\text{N}^+\text{F}^- \) (tetra-n-butyrammonium fluoride, known as TBAF and pronounced ‘tea-baff’), which is soluble in organic solvents. In fact, TBDMS is one member of a whole family of trialkysilyl protecting groups and their relative stability to nucleophiles of various kinds is determined by the three alkyl groups carried by silicon. The most labile, trimethylsilyl (TMS), is removed simply on treatment with methanol, while the most stable require hydrofluoric acid.

Although not important to our discussion here, these substitution reactions are not the simple \( S_2 \) reactions (Chapter 15) they might appear to be. The nucleophile adds to silicon first to form a five-valent anion, which decomposes with the loss of the alcohol.

Why can’t we just use a simple alkyl ether (methyl, say) to protect a hydroxyl group? There is no problem making the ether, and it will survive most reactions—but there is a problem getting an ether off again. This is always a consideration in protecting group chemistry—you want a group that is stable to the conditions of whatever reaction you are going to do (in these examples, strong bases and nucleophiles), but can then be removed under mild conditions that do not result in decomposition of a sensitive molecule. What we need then is an ether that has an Achilles’ heel—a feature that makes it susceptible to attack by some specific reagent or under specific conditions. One such group is the tetrahydropyranyl (THP) group. Although it is stable under basic conditions, as an ether would be, it is an acetal—the presence of the second oxygen atom is its Achilles’ heel and makes the THP protecting group susceptible to hydrolysis under acidic conditions. You could see the lone pair on the second oxygen atom as a safety catch that is released only in the presence of acid.

Making the THP acetal has to be done in an unfamiliar way because the usual ‘carbonyl plus two alcohols’ method is inappropriate (work out why!). Alcohols are protected by treating them with an enol ether, dihydropyran, under acid catalysis. Notice the oxonium intermediate (formed by a familiar mechanism from Chapter 12)—just as in a normal acetal-forming reaction. In this example the THP group is at work preventing a hydroxyl group from interfering in the reduction of an ester.

There is more chemistry of enol ethers in Chapter 20.
The THP-protected compound above was used as an intermediate in a synthesis of the insecticide milbemycin. It needed to be converted to the alkyne in the margin—to do this the other hydroxyl group also needed protecting.

This time, however, TBDMS will not do because the protecting group needs to withstand the acidic conditions needed to remove the THP protecting group! What is more, the protecting group needs to be able to survive acid conditions in later steps of the synthesis of the insecticide. The answer is to use a third type of hydroxyl-protecting group, a benzyl ether. Benzyl (Bn) protecting groups are put on using strong base (usually sodium hydride) plus benzyl bromide, and are stable to both acid and base.

The benzyl ether's Achilles' heel is the aromatic ring and, after reading the first half of this chapter, you should be able to suggest conditions that will take it off again: hydrogenation (hydrogenolysis) over a palladium catalyst, which cleaves benzylic C–O bonds.

Benzyl ethers can alternatively sometimes be removed by acid, if the acid has a nucleophilic conjugate base. HBr, for example, will remove a benzyl ether because Br⁻ is a good enough nucleophile to displace ROH, although only at the reactive, benzylic centre.
We said earlier that simple methyl ethers are inappropriate as protecting groups for OH because they are too hard to take off again. That is usually true, but not if the OH is phenolic—ArOH is a better leaving group than ROH, so HBr will take off methyl groups from aryl methyl ethers too.

Protecting groups may be useful, but they are also wasteful—both of time, because there are two extra steps to do (putting the group on and taking it off), and of material, because these steps may not go in 100% yield. Here’s one way to avoid using them. During the development of the anti-asthma drug salbutamol, the triol below was needed. With large quantities of salbutamol already available, it seemed most straightforward to make the triol by adding phenylmagnesium bromide to an ester available from salbutamol. Unfortunately, the ester also contains three acidic protons, making it look as though the hydroxyl and amine groups all need protecting. But, in fact, it was possible to do the reaction just by adding a large excess of Grignard reagent: enough to remove the acidic protons and to add to the ester.

This strategy is easy to try, and, providing the Grignard reagent isn’t valuable (you can buy PhMgBr in bottles), is much more economical than putting on protecting groups and taking them off again. But it doesn’t always work—there is no way of telling whether it will until you try the reaction in the laboratory. In this closely related reaction, for example, the same chemists found that they needed to protect both the phenolic hydroxyl group (but not the other alcohol OH) as a benzyl ether and the amine NH as a benzyl amine. Both protecting groups come off in one hydrogenation step.

Benzyl groups are one way of protecting secondary amines against strong bases that might deprotonate them. But it is the nucleophilicity of amines that usually poses problems of chemoselectivity, rather than the acidity of their NH groups. The potential for pitfalls is
nowhere more acute than in the synthesis of one of the most important classes of biological molecules: peptides.

**Peptide synthesis**

Peptide synthesis has become one of the most reliable and predictable fields of practical organic chemistry, principally because of the effectiveness of the protecting groups it employs. For this reason, peptides are one of the few classes of complex organic molecules that can routinely be made by machines, such as the one on the right, in which much of the chemistry we are about to talk about takes place without any human intervention.

Biology makes peptides and proteins by selectively coupling together members of a pool of 20 or so amino acids. To do the same in the laboratory, we need to overcome a number of challenges. For example, we'll start by thinking about how to react two amino acids together, to make a dipeptide—leucine and glycine, for example. If we want the NH$_2$ group of glycine to react with the CO$_2$H group of leucine we will first have to activate the carboxylic acid towards nucleophilic substitution—by making the acyl chloride, say, or a particularly reactive ester, which we will represent as RCOX.

\[
\begin{align*}
\text{Leu} & \quad \text{Gly} \\
\text{HN} & \quad \text{OH} \\
\text{CO}_2\text{H} & \quad \text{NH}_2
\end{align*}
\]

\[
\begin{align*}
\text{Leu} & \quad \text{Gly} \\
\text{HN} & \quad \text{OH} \\
\text{CO}_2\text{H} & \quad \text{NH}_2
\end{align*}
\]

The main problem, though, is that there is another free CO$_2$H, which could react with the COX group to form an anhydride, and two different free amines, either of which might react, giving both LeuLeu (which we don't want) and LeuGly (which we do).

For this reason, we need to protect both the NH$_2$ group of leucine and the CO$_2$H group of glycine. What sort of protecting groups do they need to be? We will need to be able to take them off again once they have done their job, so there is no point using, say, an amide to protect the amine since we would have great difficulty hydrolysing the amide in the presence of the amide bond we are trying to form. Not only do we want the protecting groups to be removable under mild conditions, but we want two groups (one for each of NH$_2$ and CO$_2$H) which we can take off under different conditions. We then have the opportunity to modify either end of the dipeptide at will.

\[
\begin{align*}
\text{Leu} & \quad \text{Gly} \\
\text{HN} & \quad \text{OH} \\
\text{CO}_2\text{H} & \quad \text{NH}_2
\end{align*}
\]

\[
\begin{align*}
\text{Leu} & \quad \text{Gly} \\
\text{HN} & \quad \text{OH} \\
\text{CO}_2\text{H} & \quad \text{NH}_2
\end{align*}
\]

A good choice for a pair of conditions might be acid and base—we might protect the NH$_2$ group with a protecting group we can remove only in base, and the CO$_2$H group with protection we can remove only in acid.
The amino acids

For reference, a full list of the amino acids appearing in the structure of peptides is given here, along with the codes used to describe them in abbreviated structures. The side chains are shown in black, with side chain functional groups in green. More chemistry of amino acids will follow in Chapter 42.

The Cbz protecting group—oxytocin

\[ \text{H}_2\text{N–Cys–Tyr–Ile–Gln–Asn–Cys–Pro–Leu–Gly–CONH}_2 \]

Oxytocin is a hormone involved in controlling the onset of labour in women and the subsequent release of milk. It was the first peptide hormone to be synthesized, in 1953, by du Vigneaud and Bodanszky. First, the carboxylic acid of the glycine was protected as an ethyl ester. Making an ester is the obvious way to stop CO₂H groups interfering as acids or as nucleophiles. However, simple methyl and ethyl esters may pose problems—they can still react with such nucleophiles as amines. Ethyl esters of amino acids are therefore stable only if the NH₂ group is protected. The glycine ethyl ester had to be stored as its hydrochloride salt: in effect, the –NH₂ group is ‘protected’ as –NH₃⁺.

We introduced the dipeptide LeuGly as an example because it appears at one end of the peptide hormone oxytocin. The first step in the synthesis of oxytocin is indeed the coupling of glycine (through its amino group) with leucine. This is how it was done by du Vigneaud and Bodanszky. The ‘synthetic’ version of the hormone, syntocinon (identical, of course, with the natural version isolated from human placentas, although without the dangers of biological contamination), is regularly used in modern obstetrics to induce labour in women whose babies are overdue.
A more commonly used carboxylic-acid-protecting group that is rather more stable towards attack by nucleophiles is the t-butyl ester. t-Butyl esters can be made by reacting the carboxylic acid with the cation generated from isobutene in sulfuric acid.

Steric bulk means that t-butyl esters are resistant to nucleophilic attack at the carbonyl group, and that includes hydrolysis under basic conditions (nucleophilic attack by HO⁻). But they do hydrolyse relatively easily in acid because the mechanism of hydrolysis of t-butyl esters in acid is quite different. Instead of undergoing nucleophilic attack at the carbonyl group, the t-butyl ester loses a stable carbocation, which is either captured by solvent in an S_N1 reaction or loses a proton in an E1 reaction.

In the event, the chemists needed a group that they could later react with ammonia to make the primary amide that is present in oxytocin. They also wanted a group that was stable to mild acid—so they chose the ethyl ester.

As for the leucine residue, it had to have its NH₂ group protected using a base-stable protecting group because base would be needed to release the NH₂ group of the glycine hydrochloride salt. The group that was used is one of the most important nitrogen-protecting groups and is known as the Cbz group (Cbz stands for carboxybenzyl). Cbz groups are put on by treating with benzyl chloroformate (BnOCOCl) and weak base.

Cbz-protected amines are actually carbamates: just like amides they are no longer nucleophilic because the nitrogen’s lone pair is tied up in conjugation with the carbonyl group. They are resistant to both aqueous acid and aqueous base, but they have, to use the analogy we developed earlier, an Achilles’ heel—the benzyl group. Removal of the benzyl group under the same two sets of conditions that remove benzyl ethers (p. 551) releases the safety catch and removes Cbz:

+ PhMe

The carboxylic acid of the Cbz-protected leucine next has to be activated to allow it to react with the glycine. The acyl chloride won’t do as it is unstable, and an alternative in peptide chemistry is to make a p-nitrophenyl or 2,4,6-trichlorophenyl ester. Phenoxide, especially when substituted with electron-withdrawing substituents, is a good leaving group, and Cbz-leucine p-nitrophenyl ester reacts with the glycine hydrochloride ethyl ester in the presence of a weak base (triethylamine, to release the glycine’s NH\textsubscript{2} group).

The dipeptide is now coupled—but is still protected. Deprotection (HBr/AcOH) gave the HCl salt of LeuGly ethyl ester for further reaction. The rest of the peptide was built up in much the same way—each amino acid being introduced as the Cbz-protected p-nitrophenyl ester before being deprotected ready for the next coupling, until all nine of oxytocin’s amino acids had been introduced.

The Boc protecting group—gastrin and aspartame

Gastrin is a hormone released from the stomach that controls the progress of digestion. Early work on the hormone showed that only the four C-terminal amino acids of the peptide (the C-terminal tetrapeptide) were necessary for its physiological activity.

The synthesis starts with the coupling of two more amino acids: aspartic acid and phenylalanine. As you would expect, the carboxylic acid group of phenylalanine is protected, this time as a methyl ester, and the NH\textsubscript{2} group of aspartic acid is protected as a Cbz derivative. Since aspartic acid has two carboxylic acid groups, one of these also has to be protected. Here is the method—first the Cbz group is put on; then both acids are protected as benzyl esters. Then just one of the benzyl esters is hydrolysed. It may seem surprising to you that this chemoselective hydrolysis is possible, and you could not have predicted that it would work without trying it out in the laboratory.
Accidental aspartame

At this point in one synthesis of the tetrapeptide in the laboratories of Searle, the now defunct American pharmaceutical company, a remarkable discovery occurred. The AspPhe methyl ester was accidentally found to taste sweet—extremely sweet—about 200 times as sweet as sucrose. AspPhe is now known as aspartame, marketed under the brand name NutraSweet. It goes without saying that despite this extraordinary discovery, tasting anything in the laboratory, accidentally or otherwise, is extremely unwise, ill-judged, and outright dangerous. Donald Rumsfeld was once chief executive of Searle.

The protected acid is next activated as its 2,4,6-trichlorophenyl ester, ready for coupling with the phenylalanine methyl ester in base. Now you see why the benzyl ester was chosen to protect Asp's side-chain carboxylic acid group—hydrogenolysis can be used to cleave both the Cbz group and the benzyl ester at the same time.

The next amino acid in the peptide is methionine, and it will of course need N-protecting and C-activating. The N-protecting group used this time was different—still a carbamate, although not Cbz—it was Boc, which stands for t-butyloxycarbonyl and is pronounced 'bock'. The Boc group, t-BuOCO, is introduced with (t-BuOCO)2O, known as Boc anhydride. Like Cbz, the Boc group is a carbamate protecting group. But, unlike Cbz, it can be removed simply with dilute aqueous acid. Just 3M HCl will hydrolyse it, again by protonation, loss of t-butyl cation, and decarboxylation. Base, on the other hand, cannot touch the Boc group—the carbonyl group is too hindered to be attacked even by OH−, and Boc is strongly resistant to basic hydrolysis.

The mechanism for this hydrolysis is comparable to the acid-catalysed cleavage of Cbz groups, but remember that here the t-Bu group leaves in an S N1 step. Cbz groups are cleaved by using a good nucleophile, Br−, because an S N2 step is involved; any old acid will cleave Boc.

removal of the Boc group in acid
Meanwhile, back at the tetrapeptide synthesis, methionine (Met) has been Boc-protected, and is ready for activation—as a 2,4,6-trichlorophenyl ester (abbreviated to Ar below) this time—and coupling with the deprotected AspPhe–OMe. Aqueous acid takes off the Boc group without hydrolysing peptide or ester bonds, and a repeat of this cycle with Boc-tryptophan trichlorophenyl ester (BocHN–Trp–OAr) followed by formation of the amide with ammonia finally gives the tetrapeptide.

The Fmoc protecting group

Our final protecting group has a susceptibility inverse to that of Boc. The Fmoc (pronounced ‘eff-mock’), or fluorenylmethyloxycarbonyl, protecting group cannot be lost by substitution in the manner of Cbz or t-Boc because neither S_N1 nor S_N2 mechanisms can operate at the ringed carbon atom: it is both primary and hindered.

So, where is the safety catch? Fmoc’s Achilles’ heel is its rather acidic proton (pK_a about 25), shown in green. It’s acidic because the anionic product of deprotonation is aromatic. Only a very small concentration of this aromatic anion ever forms, but as it does it immediately undergoes elimination. Fmoc-protected amines are readily deprotected in base.

In Chapter 15 we analysed in detail the structural features which favour and disfavour substitution reactions of this type.

The aromaticity of cyclopentadienyl anions of this type was discussed in Chapter 17, p. 401.
The table of protecting groups, built up slowly over this chapter, is now complete. You should from this point on be able to write a structure for each of the ones listed below, and you should also be familiar with the types of conditions necessary for protection and deprotection with each member of the list.

Chemoselective methods for oxidation and reduction, and protecting groups to help control chemoselectivity, will appear throughout this book, and we shall return in detail to peptides and their biological functions in Chapter 42. Before then we will address in detail stereoselectivity (in Chapters 32, 33, and 41) but the very next chapter will deal with the other aspect of selectivity—regioselectivity.

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Regioselectivity

Introduction

We met chemoselectivity—which group reacts—in the last chapter. Chemoselectivity means that there are two separate functional groups and that a reagent must choose between them. By contrast, regioselectivity implies that there is one functional group that can react in two different places and a reagent must choose where to react. Simple examples include addition of HX to an alkene (Chapter 19) and nucleophilic attack on the epoxide derived from that alkene (Chapter 15).

It might also mean that two functional groups are combined in a single conjugated system that can again react in two (or more) places. Examples include the addition of bromine to dienes (two conjugated alkenes) and addition of a nucleophile to a conjugated carbonyl compound (carbonyl group conjugated to an alkene).
The choice between ortho/para and meta substitution when an electrophile attacks a benzene ring (Chapter 21) is also a matter of regioselectivity. We shall discuss all these examples in further detail in this chapter, and extend these ideas to new reactions as well.

**Regioselectivity in electrophilic aromatic substitution**

We start with electrophilic aromatic substitution. It was established in Chapter 21 that an electron-donating substituent favours ortho/para and an electron-withdrawing substituent favours meta substitution. Although meta substitution is usually slower than ortho/para substitution (because electron-withdrawing groups deactivate the ring), it usually gives the meta product alone.

![Reaction Scheme](image)

Most reactions of benzene rings with electron-donating substituents give ortho/para mixtures and, if the substituent is very electron-donating, may lead to both ortho and para substitution in the same molecule. Control in favour of the para product can usually be achieved by reducing the reactivity of the substituent and increasing its size.

![Reaction Scheme](image)

Of course, if the para position is blocked, ortho substitution is the only option, and we will come back to the idea of blocking substituents shortly. But there is a general way of directing electrophiles to the ortho position using activation by metallation.

![Reaction Scheme](image)

**Making organometallics by deprotonating aromatic rings: ortholithiation**

Look at the reaction below: butyllithium deprotonates an sp² hybridized carbon atom to give an aryllithium. It works because the protons attached to sp² carbons are more acidic than protons attached to sp³ carbons (although they are a lot less acidic than alkyne protons).

![Reaction Scheme](image)

But there must be another factor involved to account for exclusive ortho substitution, which is after all the most hindered site. The functional group containing oxygen (sometimes nitrogen) is next to the proton to be removed. This functional group 'guides' the butyllithium, so that it attacks the adjacent protons. It does this by forming a complex with the Lewis acidic lithium atom, much as ether solvents dissolve Grignard reagents by complexing.
their Lewis-acidic metal ions. This mechanism means that it is only the protons ortho to the functional group that can be removed, and the reaction is known as an ortholithiation.

The example below shows ortholithiation, activated by the nitrogen atom of a tertiary amine, being used to make a new C–C bond. Here it is the nitrogen atom that directs attack of the butyllithium, again by complexation with the Li atom.

Ortholithiation is a useful way of making reactive organometallics because the starting material does not need to contain a halogen atom. But it is much less general than the other ways we have told you about for making organolithiums, as there are rather tight restrictions on what sorts of groups the aromatic ring must carry. The best ortholithiation-directing substituents have lone pairs to donate electrons to Li and are also electronegative so they withdraw electrons from the benzene ring and help stabilize the anion forming at the ortho position.

Fredericamycin

Fredericamycin is a curious aromatic compound extracted in 1981 from the soil bacterium Streptomyces griseus. It is a powerful antibiotic and antitumour agent, and its structure is shown below. The first time it was made in the laboratory, in 1988, the chemists in Boston started their synthesis with three consecutive lithiation reactions: two are ortholithiations, and the third is slightly different. You needn’t be concerned about the reagents that react with the organolithiums; just look at the lithiation reactions themselves. In each one, one or more oxygen atoms (colour-coded green) directs a strongly basic reagent to remove a nearby proton (colour-coded black). As it happens, none of the steps uses n-BuLi itself, but instead its more reactive cousins, sec-BuLi and tert-BuLi (see the table on p. 186). The third lithiation step uses a different kind of base related to LDA, made by deprotonating an amine (pKₐ about 35). The black proton removed in this third lithiation is more acidic because it is next to an aromatic ring.
**Sulfonation may lead to ortho selectivity without lithiation**

We introduced sulfonation in Chapter 21 but have left detailed discussion until now because sulfonation has some features that make it more interesting than first meets the eye. One important difference between sulfonation and other examples of electrophilic substitution is that sulfonation is reversible. Heating an arenesulfonic acid causes it to decompose with loss of gaseous SO₃.

Here’s an example of how we can exploit this to gain control of regioselectivity without resorting to lithiation. In stage 1 the phenol is sulfonated twice—the first sulfonic acid group (which adds para to the OH group) is electron-withdrawing and deactivates the ring, making the introduction of the second group (which goes ortho to the OH and meta to the first sulfonic acid) harder and that of the third group harder still, which is why we can isolate the disulfonated phenol.

![Sulfonation reaction](image)

In the second stage, the bromination, the OH directs to the ortho and para positions, but only one ortho position is vacant, so the bromine attacks there. Sodium hydroxide is needed to deprotonate the sulfonic acid groups to make them less deactivating. The sulfonation reaction is reversible, and in the third stage it is possible to drive the reaction over to the products by distilling out the relatively volatile 2-bromophenol at high temperature. The loss of SO₃ involves attack of H⁺ on the aromatic ring.

![Bromination reaction](image)

Overall, we have succeeded in making 2-bromophenol where direct bromination of phenol itself would have given (at low temperatures) mainly p-bromophenol and at higher temperatures, 2,4,6-tribromophenol. The sulfonic acid groups are useful reversible blocking groups.

The same method can be used with anilines because para-sulfonation of aromatic amines is possible. This seems surprising because in sulfuric acid essentially all the amine will be protonated. You might expect the resulting ammonium ion to react in the meta position (because NH₃⁺ is no longer electron-rich) but instead the para-sulfonic acid (sulfanilic acid) is formed. At the high temperature of the reaction, it is probable that any meta-substituted product reverts to the starting material, while the para-sulfonic acid accumulates because it is stabilized by delocalization and is less hindered.

![Aniline sulfonation reaction](image)

**Regioselective reactions of naphthalene**

We introduced you to the 10-electron aromatic system of naphthalene in Chapter 7. As you would expect, it undergoes electrophilic aromatic substitution with the same reagents you met in Chapter 21, but the regioselectivity of its reactions is of a different type to the ortho, meta,
para selectivity we have been talking about. Naphthalene has 10 carbons: two form the ring junction, and aren’t available for substitution reactions, and the other eight are of just two types $\alpha$ (the 1-position, next to the ring junction) and $\beta$ (the 2-position).

Electrophilic substitution on naphthalene normally occurs at a site next to the ring junction ($\alpha$). This is because the HOMO has its largest coefficient at this atom, but you can rationalize the result by looking at the long, linear delocalization in the resulting cation, which can be represented by a single train of arrows. This extended conjugation makes naphthalene more nucleophilic than benzene. So, bromination occurs at the $\alpha$-position in good yield even without a Lewis acid.

Reaction at the other position ($\beta$) is less favourable as the intermediate cation is cross-conjugated. The cation delocalizes into both rings, but no long linear chain of arrows is possible.

If the reaction is irreversible, the $\alpha$-product is usually formed. But if the reaction is reversible, as is the case with sulfonation, the position of substitution may be determined by temperature. Sulfonation at low temperatures gives the $\alpha$-product by kinetic control, while sulfonation at high temperatures gives the $\beta$-product by thermodynamic control. The $\beta$-product is formed more slowly but it is more stable as there is less steric hindrance between the large sulfonic acid group and the orange hydrogen on the other ring. Under conditions allowing reversible sulfonation, eventually all the product ends up $\beta$.

Regiocontrol by choice of route

Choosing the right route to an aromatic product is essential if you want to get one particular isomer. We can illustrate this with the synthesis of the isomers of bromonitrobenzene. Because the bromo substituent is ortho, para-directing and the nitro group meta-directing, it’s possible to make all three isomers, providing we exploit the regioselectivity of electrophilic substitution. Nitration of bromobenzene would give the ortho and para isomers while bromination of nitrobenzene would give the meta isomer. The selectivity of the first reaction is not good: bromine is small and not very electrophilic, so steric hindrance is weak and the ortho positions are not deactivated. Furthermore there are two ortho positions but only one para: a typical result is about 37% ortho, 1% meta, and 62% para. Both compounds are industrial products, made by nitration and separated.
Bromination of nitrobenzene is remarkably good, considering the unreactivity of nitrobenzene in electrophilic aromatic substitution. One recipe uses iron powder and bromine at 140 °C and gives 74% of the meta product. We shall need these reactions in the next section.

Before we move on, consider why this selectivity works: we can get all three isomers because we have one ortho/para director and one meta director. But what if we had two ortho/para directors—say, amino and bromo—and wanted the meta isomer?

The solution in these cases is often to make use of the transformation of the nitro group (a meta director) into an amino group (a para director) by reduction.

Since the amino group can be substituted by diazotization (p. 520), many problems of regioselectivity can be solved by using nitro compounds as intermediates. You could, for example, use the product above to make the otherwise challenging 3-bromoiodobenzene:

**Regioselectivity in nucleophilic aromatic substitution**

As you saw in Chapters 21 and 22, diazonium salts need no activation to undergo nucleophilic aromatic substitution, but for other leaving groups a nitro group is commonly used as an activator. The three fluoronitrobenzenes are all commercial products but only the ortho and para isomers can do the nucleophilic substitution. This is because the nitro group must be able to stabilize the addition intermediate by accepting the negative charge.

By carefully combining electrophilic and nucleophilic substitution it is possible to make aromatic compounds with substituents arranged in a precise and predictable fashion. So, if we nitrates o-dichlorobenzene, all positions are favourable but the nitro group goes in para to one Cl atom because of steric hindrance at the ortho positions. Although chlorine is small, two chlorines next to each other have a butressing effect as each pushes the other away. It is difficult to get three adjacent substituents on a benzene ring. If we now do a nucleophilic
aromatic substitution, only the Cl para to the nitro group is displaced. We can even reduce the nitro group to the corresponding amine.

The last successful method for nucleophilic aromatic substitution uses a benzyne intermediate—on p. 524 you saw benzyne chemistry being used to make meta-aminoanisole, like this:

Now that the amino group is fixed; we can displace it via a diazonium salt using any chosen nucleophile—copper cyanide for example:

Regioselectivity of intramolecular reactions

A cunning way to get unusual regioselectivity is to make the reaction intramolecular. The synthesis from benzene of the cyclic ketone known as tetralone may look difficult as we must get an ortho relationship on the benzene ring. But if we make the final bond in the ring by a Friedel–Crafts acylation there is no problem. The alkyl group is ortho,para-directing and the acid cannot reach the para position.

Notice the use of a cyclic anhydride in the first Friedel–Crafts acylation. It doesn't matter where the acylation occurs and the reaction stops there as the ring is deactivated by the ketone and the carboxylic acid released in the reaction is much less electrophilic than the anhydride. The ketone is then reduced to a CH₂ group by the Clemmensen method (see Chapter 23) and polyphosphoric acid is used to carry out the intramolecular acylation step.

A more subtle approach is to use a ‘tether’—something that holds two reagents together and is afterwards cleaved. An example is halolactonization. The idea is simple. A halogen, say bromine, attacks an alkene and the bromonium ion intermediate is captured intramolecularly by the anion of a carboxylic acid. The reaction therefore uses bromine and NaHCO₃—a weak base, but one strong enough to deprotonate a carboxylic acid. The anion attacks the more highly substituted end of the bromonium ion, as explained in Chapter 19, and forms a five-membered ring.

Usually a more powerful catalyst (AlCl₃) is needed, but intramolecular acylations are fast enough without this.
Although any halogen might be used in this reaction, iodine is the most versatile and the reaction is commonly called iodolactonization. The tether is the C–O bond of the lactone and this can be cleaved with an alkoxide.

The reaction with methoxide needs some explanation. Attack on the carbonyl group cleaves the lactone, releasing an alkoxide that cyclizes to form an epoxide. A second molecule of methoxide now attacks the epoxide, opening it from the less hindered end as we should expect in an anionic reaction (Chapter 19).

Another example shows that reaction may occur at the other end of the iodonium ion. Attack at the tertiary carbon would be difficult sterically and, in any case, would give an unstable four-membered ring. The lactone formed has the iodine β to the carbonyl group and so eliminates easily in base (pyridine works well) by the E1cB mechanism (Chapter 17) to give the unsaturated lactone. Although the relative stereochemistry of the iodolactone is controlled by the inversion in the opening of the iodonium ion, it is irrelevant as it disappears in the elimination step.

Regioselectivity in elimination reactions

This question was discussed in Chapter 17 but we can return to it here with more sophisticated examples. The regioselectivity in the last reaction of the sequence above dictates the position of the alkene in the product. Of all of the protons adjacent to the iodo group, only a black one is lost:

The orange hydrogen cannot be lost by E2 as it is cis to the iodine and E2 reactions prefer a trans (anti-periplanar) arrangement. The green hydrogens are not lost because they are less acidic than the black hydrogens. In fact, this is not an E2 elimination at all. Because one of the black hydrogens can be lost in enolate formation, this is an E1cB elimination.
But now another regioselectivity question arises: if elimination occurs preferably towards the carbonyl group, how can we make the starting material for the iodolactonization sequence, which has the alkene not in conjugation with the carboxylic acid? It turns out that it is better to make the ester with the ‘wrong’ regioselectivity. This is easily done by a Horner–Wadsworth–Emmons reaction using a phosphonate ester. This Wittig-style reaction is explained in Chapter 27.

\[
\text{O} \quad \xrightarrow{\text{NaH}} \quad \text{(EtO)}_2\text{P} \quad \xrightarrow{\text{O}} \quad \text{CO}_2\text{Et} + \quad \text{O} \quad \xrightarrow{\text{NaH}} \quad \text{(EtO)}_2\text{P} \quad \xrightarrow{\text{O}} \quad \text{CO}_2\text{Et}
\]

Now comes the remarkable regioselectivity. The ester is hydrolysed, as usual, in aqueous NaOH. On acidification to pH 3, the free acid is released and the double bond has moved into the ring.

\[
\text{CO}_2\text{Et} \quad \xrightarrow{\text{NaOH}} \quad \text{H}_2\text{O} \quad \xrightarrow{\text{pH 3}} \quad \text{CO}_2\text{H}
\]

Alkenes like to be conjugated with carbonyl groups but they also prefer to be inside six-membered rings rather than outside—in this case presumably because the ester group otherwise has to eclipse a ring carbon. Conjugation with an ester group pulls the alkene out of the six-membered ring in the lactone we made above, but when the carbonyl group is a carboxylate anion, conjugation is very weak and the double bond moves into the ring.

**Electrophilic attack on alkenes**

You met electrophilic attack on alkenes in Chapter 19 and we shall just briefly revisit its regioselectivity. Unsymmetrical alkenes add HBr to give the more stable of the two possible cations. If R is alkyl or aryl, this means the more substituted cation.

\[
\text{unstable primary cation not formed}
\]

If you want to get the other regioisomer, with the heteroatom at the end, you can use hydroboration (Chapter 19) or the radical reactions described in the next section. Here is a brief reminder of hydroboration. Reaction between a borane having at least one B–H bond with an alkene gives an alkyl borane in which all the hydrogens are replaced by alkyl groups. Oxidation gives the terminal alcohol.

\[
\text{R} \quad \xrightarrow{\text{BH}_3} \quad \text{BH}_2 \quad \xrightarrow{\text{BH}_3} \quad \text{BH}_3 \quad \xrightarrow{\text{H}_2\text{O}_2 \text{NaOH}} \quad \text{OH} + \text{NaB(OH)}_4
\]

The regioselectivity comes from the first step. The boron’s empty p orbital bonds to the more nucleophilic end of the alkene and hydride is transferred to give a borane. Reaction with alkaline H$_2$O$_2$ leads to migration of an alkyl group from boron to oxygen and eventually to the alcohol.
Borane is unstable but can easily be made from NaBH₄ and BF₃. In this synthesis of hexan-1-ol from hex-1-ene, a water molecule has been added to the alkene, but with the opposite regioselectivity to reactions with H₂O in acid or HBr.

\[ \text{NaBH}_4, \text{BF}_3, \text{OEt}_2 \rightarrow \text{B} \rightarrow \text{H}_2\text{O}_2, \text{NaOH} \rightarrow \text{OH} \]

\[ \text{81\% yield} \]

**Regioselectivity in radical reactions**

Almost every reaction we have discussed so far has been ionic, but in this short section we need to give you a preview of another group of reactions we return to in Chapter 37—those of radicals. When HBr adds to an unsymmetrical alkene we use arrows that represent the movement of two electrons to give charged intermediates that combine in a second step to give a neutral product. The strong H–Br bond breaks to give a bromide ion and a stable alkyl cation. This bond breaks *heterolytically*—that is, unsymmetrically—as does the alkene bond. We can predict the regiochemistry of these reactions by making the most stable anions and cations as intermediates, in this case a tertiary alkyl cation and a bromide anion.

![Radical addition](image)

**Radical addition**

The regioselectivity in the reaction below is opposite: a primary alkyl bromide is formed, by a different mechanism involving radicals.

In radical reactions, bonds break *homolytically* with one electron going one way and one the other. The radicals that are formed have an odd number of electrons, one of which must be unpaired. This makes them very reactive and they are not usually isolated. Even strong bonds can break into ions provided they are polarized, but to make radicals we need weak symmetrical bonds such as O–O, Br–Br or I–I. Dibenzoyl peroxide, the Ph(CO₂)₂ catalyst in this reaction, readily undergoes homolysis like this—the one-electron movements are represented by ‘fish-hook’ arrows having one barb and odd electrons on atoms are represented by dots.

\[ \text{dibenzoyl peroxide} \rightarrow \text{Ph CO} \cdot \text{O} - \text{O} \text{Ph} \rightarrow \text{Ph CO} \cdot \text{O} + \cdot \text{O Ph} \]

\[ \Delta G^\ddagger = 139 \text{ kJ mol}^{-1} \]

Now we can use the new radicals we have just made to cleave the strong HBr bond homolytically because a new and very strong OH bond will be formed. As we start with one radical intermediate that must have an unpaired electron, we must finish with another radical with an unpaired electron. In this case, it is a bromine radical.

\[ \text{Ph CO} \cdot \text{O} + \text{H} - \text{Br} \rightarrow \text{Ph CO} \cdot \text{OH} + \text{Br}^- \]

If we do this reaction in the presence of the alkene we have just reacted with HBr, the bromine radical adds to the alkene in one of the two possible ways. Although radicals are neutral,
they are electron-deficient (the C atom is one electron short) and, rather like cations, are more stable the more substituents they have. So the tertiary radical is formed rather than the primary radical, and the bromine ends up at the primary position.

We have still not reached the end of the reaction as our product is still a radical. How can it become a molecule with only paired electrons? The answer is simple. It reacts with another HBr molecule to produce more bromine radicals. Now you see something important to all radical reactions: only a small amount of the radical is needed as more radicals are produced every time the reaction gives product. The overall process is a radical chain reaction.

Because of this we also need only very small amounts of dibenzoyl peroxide, the radical initiator, which is just as well as it is potentially explosive, like many radical generators. Here is the reaction being used to make a bromoacid:

Radical abstraction

We sneaked a new reaction into that sequence. The removal of a hydrogen atom (note: not a proton) from HBr by the peroxide radical is an abstraction reaction. The bromine radical will also abstract hydrogen atoms and will do so from the same alkene we have just used but with yet another different outcome, as you see in the margin.

When light shines on bromine, the weak Br–Br bond breaks to give two bromine radicals. Heat will do the job too but light is cleaner and, as bromine is brown, it absorbs most wavelengths of visible light.

Radicals are very unstable and reactive, and these bromine radicals may simply recombine or they may react with other compounds. You already know that bromide anions are good nucleophiles in $S_N2$ reactions, but bromine radicals do two quite different reactions: abstraction and addition. The Br radical may abstract a hydrogen atom from the alkene or it may add to the $\pi$ bond. Notice that each reaction produces a new carbon-centred radical and, in the first case, a molecule of HBr. Whereas the Br–Br bond is weak, the H–Br bond is much stronger ($366 \text{ kJ mol}^{-1}$) and, unlike ionic reactions, radical reactions are dominated by bond strength.

The first reaction introduces another important aspect of regioselectivity: why does the radical abstract that H atom, and not one from the alkene?
Removal of an alkene H gives a carbon-centred radical localized on the sp² atom but the removal of an H from a methyl group gives a much more stable delocalized allylic radical. In addition there are six such H atoms but only two alkene H atoms.

The reaction obviously cannot end there with the formation of another radical, however stable, and this allylic radical collects a bromine atom from a bromine molecule. Note that the allylic radical doesn’t react with a bromine radical in this step: radicals are very unstable and the concentration of radicals at any one time is so low that it is rare for two of them to meet.

This step also produces a new bromine radical that can start a new series of reactions. Like the addition of HBr above, the reaction is a radical chain reaction, and only a small amount of Br₂ needs to break down to Br• to get the reaction going. This is important as you already know what happens when bromine molecules react with alkenes: addition occurs by an ionic mechanism. Add too much Br₂ and the bromine molecules attack the alkene directly and do not abstract H atoms.

If we want to make the dibromide, we use plenty of bromine, but if we want to use a radical process to make the allylic bromide we must take advantage of the greater reactivity of the radical and keep the bromine concentration low. A good way to do this is to use the compound NBS (N-bromosuccinimide), which you met in Chapter 19. NBS acts as a sort of turnstile which only lets a molecule of Br₂ out when a molecule of HBr is formed (and of course HBr is the by-product in the radical bromination).

Br₂ is slowly released into the reaction as it proceeds, and the concentration never builds up enough to generate the dibromide. In this example, dibenzoyl peroxide is the initiator and allylic bromination gives the useful cyclohexenyl bromide.

These radical reactions will be described in much greater detail in Chapter 37. For the moment you need only notice that they can have quite different regioselectivity from ionic reactions with the same reagents.
Nucleophilic attack on allylic compounds

The allylic bromides that can be made by these radical reactions display interesting regioselectivity. We shall start with some substitution reactions with which you are familiar from Chapter 15. There we said that allyl bromide is about 100 times more reactive towards simple SN2 reactions than is propyl bromide or other saturated alkyl halides.

The double bond stabilizes the SN2 transition state by conjugation with the p orbital at the carbon atom under attack. This full p orbital (shown in orange in the diagram below) forms a partial bond with the nucleophile and with the leaving group in the transition state. Any stabilization of the transition state will, of course, accelerate the reaction by lowering the energy barrier.

There is an alternative mechanism for this reaction that involves nucleophilic attack on the alkene instead of on the saturated carbon atom. This mechanism leads to the same product and is often called the SN2’ (pronounced ‘S-N-two-prime’) mechanism.

We can explain both mechanisms in a unified way if we look at the frontier orbitals involved. The nucleophile must attack an empty orbital (the LUMO), which we might expect to be simply $\sigma^*$ ($C-Br$) for the SN2 reaction. But this ignores the alkene. The interaction between $\pi^*$ ($C=C$) and the adjacent $\sigma^*$ ($C-Br$) will as usual produce two new orbitals, one higher and one lower in energy. The lower-energy orbital, $\pi^* + \sigma^*$, will now be the LUMO. To construct this orbital we must put all the atomic orbitals parallel and make the contact between $\pi^* + \sigma^*$ a bonding interaction.
If the allylic halide is unsymmetrically substituted, a question of regioselectivity arises. The products from $S_N2$ and $S_N2'$ are different and the normal result is that nucleophilic attack occurs at the less hindered end of the allylic system, whether that means $S_N2$ or $S_N2'$. This important allylic bromide, known as prenyl bromide, normally reacts entirely via the $S_N2$ reaction.

The two ends of the allylic system are contrasted sterically: direct ($S_N2$) attack is at a primary carbon while allylic ($S_N2'$) attack is at a tertiary carbon atom so that steric hindrance favours the $S_N2$ reaction. In addition, the number of substituents on the alkene product means that the $S_N2$ product is nearly always preferred—$S_N2$ gives a trisubstituted alkene while the $S_N2'$ product has a less stable monosubstituted alkene.

An important example is the reaction of prenyl bromide with phenols. This is simply carried out with $K_2CO_3$ in acetone as phenols are acidic enough ($pK_a \approx 10$) to be substantially deprotonated by carbonate. The product is almost entirely from the $S_N2$ route, and is used in the Claisen rearrangement (Chapter 35).

If we make the two ends of the allyl system more similar, say one end primary and one end secondary, things are more equal. We could consider the two isomeric butenyl chlorides.

All routes look reasonable, although we might again expect faster attack at the primary carbon. The reactions in the left-hand box are preferred to those in the right-hand box. But there is no special preference for the $S_N2$ over the $S_N2'$ mechanism or vice versa—the individual case decides. If we react the secondary butenyl chloride with an amine we get the $S_N2'$ mechanism entirely.

If the primary chloride is used, once again we get nucleophilic attack at the primary centre. The more stable product with the more highly substituted alkene is formed this time by the $S_N2$ reaction. Here is a slightly more advanced example:
Notice that these reactions take place with allylic chlorides. We should not expect an alkyl chloride to be particularly good at $S_{N2}$ reactions as chloride ion is only a moderate leaving group and we should normally prefer to use alkyl bromides or iodides. Allylic chlorides are more reactive because of the alkene. Even if the reaction occurs by a simple $S_{N2}$ mechanism without rearrangement, the alkene is still making the molecule more electrophilic.

You might ask a very good question at this point. How do we know that these reactions really take place by $S_{N2}$ and $S_{N2}'$ mechanisms and not by an $S_{N1}$ mechanism via the stable allyl cation? Well in the case of prenyl bromide, we don’t! In fact, we suspect that the cation probably is an intermediate because prenyl bromide and its allylic isomer are in rapid equilibrium in solution at room temperature.

The equilibrium is entirely in favour of prenyl bromide because of its more highly substituted double bond. Reactions on the tertiary allylic isomer are very likely to take place by the $S_{N1}$ mechanism: the cation is stable because it is tertiary and allylic and the equilibration tells us it is already there. Even if the reactions were bimolecular, no $S_{N2}'$ mechanism would be necessary for the tertiary bromide because it can equilibrate to the primary isomer more rapidly than the $S_{N2}$ or $S_{N2}'$ reaction takes place.

Even the secondary system we also considered is in rapid equilibrium when the leaving group is bromide. This time both allylic isomers are present, and the primary allylic isomer (known as crotyl bromide) is an $E/Z$ mixture. The bromides can be made from either alcohol with HBr and the same ratio of products results, indicating a common intermediate in the two mechanisms. You saw at the beginning of Chapter 15 that this reaction is restricted to alcohols that can react by $S_{N1}$.

Displacement of the bromide by cyanide ion, using the copper(I) salt as the reagent, gives a mixture of nitriles in which the more stable primary nitrile predominates even more. These can be separated by a clever device. Hydrolysis in concentrated HCl is successful with the predominant primary nitrile but the more hindered secondary nitrile does not hydrolyse. Separation of compounds having two different functional groups is easy: in this case the acid can be extracted into aqueous base, leaving the neutral nitrile in the organic layer.

Once again, we do not know for sure whether this displacement by cyanide goes by the $S_{N1}$ or $S_{N2}'$ mechanism, as the reagents equilibrate under the reaction conditions. However, the
chlorides do not equilibrate and so, if we want a clear-cut result on a single well-defined starting material, the chlorides are the compounds to use. But you already see that regioslectivity with allylic compounds may depend on steric hindrance, rates of reaction, and stability of the product.

**Regiospecific preparation of allylic chlorides**

Allylic alcohols are good starting materials for making allylic compounds with control over where the double bond and the leaving group will be. Allylic alcohols are easily made by addition of Grignard reagents or organolithium compounds to enals or enones (Chapter 9) or by reduction of enals or enones (Chapter 23). More to the point, they do not equilibrate except in strongly acidic solution, so we know which allylic isomer we have.

\[
\begin{align*}
R\text{OH} & \quad \text{MeSO}_2\text{Cl}, \text{LiCl} \\
& \quad \text{DMF, base} \\
\rightarrow \\
R\text{Cl} & \quad \text{S}_{\text{N}2}
\end{align*}
\]

Conversion of the alcohols into the chlorides is easier with the primary than with the secondary alcohols. We need to convert OH into a leaving group and provide a source of chloride ion to act as a nucleophile. One way to do this is with methanesulfonyl chloride (MeSO$_2$Cl) and LiCl.

\[
\begin{align*}
R\text{OH} & \quad \text{MeSO}_2\text{Cl}, \text{LiCl} \\
& \quad \text{DMF, base} \\
\rightarrow \\
R\text{Cl} & \quad \text{S}_{\text{N}2}
\end{align*}
\]

This result hardly looks worth reporting and, anyway, how do we know that equilibration or $S_{\text{N}1}$ reactions aren't happening? Well, here the mechanism must be $S_{\text{N}2}$ because the corresponding $Z$-allylic alcohol preserves its alkene configuration. If there were equilibration of any sort, the $Z$-alkene would give the $E$-alkene because $E$- and $Z$-allylic cations are not geometrically stable.

\[
\begin{align*}
\text{E alcohol} & \quad \text{MeSO}_2\text{Cl}, \text{LiCl} \\
& \quad \text{DMF, base} \\
\rightarrow \\
\text{E chloride} & \quad \text{S}_{\text{N}2}
\end{align*}
\]

S我相信, 这个方法没有保留的完整性 secondary allylic alcohol, which gives a mixture of allylic chlorides.

\[
\begin{align*}
\text{OH} & \quad \text{MeSO}_2\text{Cl}, \text{LiCl} \\
& \quad \text{DMF, base} \\
\rightarrow \\
\text{Cl} & \quad \text{about 3:1}
\end{align*}
\]

Reliable clean $S_{\text{N}2}$ reactions with secondary allylic alcohols can be achieved only with Mitsunobu chemistry. Here is a well-behaved example with a $Z$-alkene. The reagents have changed since your last encounter with a Mitsunobu-type reaction: instead of DEAD and a carboxylic acid we have hexachloroacetone, with, of course, triphenylphosphine.

\[
\begin{align*}
\text{OH} & \quad \text{ClC\text{CCl}_3} \\
& \quad \text{Ph}_3\text{P} \\
\rightarrow \\
\text{Cl} & \quad \text{about 3:1}
\end{align*}
\]
The first thing that happens is that the lone pair on phosphorus attacks one of the chlorine atoms in the chloroketone. The leaving group in this SN₂ reaction at chlorine is an enolate, which is a basic species and can remove the proton from the OH group in the allylic alcohol.

Now the alkoxide anion can attack the positively charged phosphorus atom. This is a good reaction in two ways. First, there is the obvious neutralization of charge and, second, the P–O bond is very strong.

The next step is a true SN₂ reaction at carbon as the very good leaving group is displaced. The already strong P–O single bond becomes an even stronger P=O double bond to compensate for the loss of the strong C–O single bond. There is obviously no SN₁ component in this displacement (otherwise the Z-alkene would have partly isomerized to the E-alkene) and very little SN₂' presumably as only 0.5% of the rearrangement product is formed. These displacements of Ph₃P=O are often the ‘tightest’ of SN₂ reactions.

Now for the really impressive result. Even if the alcohol is secondary, and the rearranged product would be thermodynamically more stable, very little of it is formed and almost all the reaction is clean SN₂.

There is a bit more rearrangement than there was with the other isomer but that is only to be expected. The very high proportion of direct SN₂ product shows that there is a real preference for the SN₂ over the SN₂' reaction in this displacement.

Now that we know how to make allylic chlorides of known structure—whether primary or secondary—we need to discover how to replace the chlorine with a nucleophile with predictable regioselectivity. We have said little so far about carbon nucleophiles (except cyanide ion) so we shall concentrate on simple carbon nucleophiles in the SN₂' reaction of allylic chlorides.

The SN₂' reaction of carbon nucleophiles on allylic chlorides

Ordinary carbon nucleophiles such as cyanide or Grignard reagents or organolithium compounds fit the patterns we have described already. They usually give the more stable product by SN₂ or SN₂' reactions depending on the starting material. If we use copper compounds, there is a tendency—no more than that—to favour the SN₂ reaction. You will recall that copper(I) was the metal we used to ensure conjugate addition to enones (Chapter 22) and its use in SN₂ reactions is obviously related. Simple alkyl copper reagents (RCu, known as Gilman reagents) generally favour the SN₂' reaction but we can do much better by using RCu complexed with BF₃.

The nature of metal–alkene complexes is discussed in Chapter 40.
The copper must complex to the alkene and then transfer the alkyl group to the $S_N2'$ position as it gathers in the chloride. This might well be the mechanism, although it is often difficult to draw precise mechanisms for organometallic reactions.

The secondary allylic isomer also gives almost entirely the rearranged product. This is perhaps less surprising, as the major product is the more stable isomer, but it means that either product can be formed in high yield simply by choosing the right (or should we say wrong, since there is complete allylic rearrangement during the reaction) isomer. The reaction is regiospecific.

The most remarkable result of all is that prenyl chloride gives rearranged products in good yield. This is about the only way in which these compounds suffer attack at the tertiary centre by $S_N2'$ reaction when there is the alternative of an $S_N2$ reaction at a primary centre.

Electrophilic attack on conjugated dienes

Another way to make allylic chlorides is by treating dienes with HCl. Electrophiles attack conjugated dienes more readily than they do isolated alkenes. There was some discussion of this in Chapter 19, establishing the main point that the terminal carbon atoms are the most nucleophilic and that the initial attack produces an allylic cation. A simple example is the addition of HCl to cyclopentadiene.

Although there is a question of regioselectivity in the initial protonation, the allylic cation is symmetrical and attack by chloride at either end produces the same product. However, if the electrophile is a halogen rather than HCl or HBr then the reaction becomes regioselective as the cationic intermediate is no longer symmetrical. What happens is this:

The alternative is direct attack on the bromonium ion intermediate, which we assume would occur at the allylic site (black arrows) and not at the other (green arrows). Although this 1,2-dibromide product is not observed, it is still possible that this reaction happens because the 1,2-product can rearrange by bromide shift to the observed 1,4-dibromide.

By ‘bromide shift’ we mean the reversible isomerization of allylic bromides you saw on p. 576.
The final product of this reaction could in fact be either of two compounds as the two bromine atoms may be cis or trans. Bromination in chloroform at \(-20\, ^\circ\text{C}\) gives mostly a liquid cis dibromide while reaction in hydrocarbon solvents gives the crystalline trans isomer. On standing the cis isomer slowly turns into the trans.

This suggests that the cis bromide is the kinetic product and the more stable trans compound is the thermodynamic product, formed by reversible loss of bromide and reformation of the bromonium ion.

Similar questions arise when nucleophilic substitution occurs on the dibromides. Reaction of either the cis or the trans dibromide with dimethylamine gives the trans isomer of a diamine. But look at the regioselectivity—it’s not the diamine you might expect. The only explanation is one SN2 displacement and one SN2' displacement.

But what about the stereochemistry? Starting with the cis isomer, one SN2 displacement with inversion might be followed by an intramolecular SN2' displacement and finally another SN2 displacement with inversion at the allylic centre.

The reaction with the trans isomer is almost identical: the same three-membered ring is an intermediate in both sequences so the products are bound to be the same.

If the nucleophile is different from the electrophile we can get a bit more information about the course of the reaction. When butadiene is treated with bromine in methanol as solvent, two adducts are formed in a 15:1 ratio along with some dibromide. Methanol is a weak nucleophile and adds to the bromonium ion mainly at the allylic position (black arrow below); only a small amount of product is formed by attack at the far end of the allylic system. Note that no attack occurs at the other end of the bromonium ion (green dotted arrow).
Conjugate addition

In Chapter 22 we devoted considerable space to discussing conjugate addition and the reasons why some reactions occur by direct attack on the carbonyl group of an α,β-unsaturated carbonyl compound and why others occur by conjugate addition. We shall briefly revise the regioselectivity aspects of these reactions.

Direct (or 1,2) addition means that the nucleophile attacks the carbonyl group directly. An addition compound is formed which may lose X⁻, if it is a leaving group, or become protonated to give an alcohol.

Conjugate (or 1,4) addition means that the nucleophile adds to the end of the alkene furthest from the carbonyl group. The electrons move through into the carbonyl group to produce an enolate anion that usually becomes protonated to give a ketone.

The first difference between the two routes is that the product from direct addition keeps the alkene but loses the carbonyl group while conjugate addition keeps the carbonyl group but loses the alkene. As a C=O π bond is stronger than a C=C π bond, **conjugate addition gives the thermodynamic product.** But as the carbonyl group is more electrophilic than the far end of the alkene, especially to charged, hard nucleophiles, **direct addition gives the kinetic product.** So direct addition is favoured by low temperatures and short reaction times while conjugate addition is favoured by higher temperatures and longer reaction times, provided the 1,2 addition is reversible.

The second difference depends on how electrophilic is the α,β-unsaturated carbonyl compound. The more electrophilic such as aldehydes and acid chlorides tend to prefer direct addition while the less electrophilic such as ketones or esters tend to prefer conjugate addition.
It is similar with the choice of nucleophile: more nucleophilic species, such as MeLi or Grignard reagents, prefer direct addition, particularly as they react irreversibly, while less nucleophilic species like amines and thiols prefer conjugate addition. These nucleophiles add reversibly to the C=O group, giving an opportunity for any direct addition product to revert to starting materials and react again.

![Diagram of conjugate and direct addition]

**Regioselectivity in action**

We finish with an example that illustrates several aspects of chemoselectivity as well as introducing the subjects of the next two chapters. The first synthetic sweetener was saccharin but newer ones such as the BASF compound thiophenesaccharin are much in demand. The sodium salt is the active sweetener but the neutral compound has to be made via the simpler intermediate thiophene.

![Structures of saccharin, salt of thiophenesaccharin, thiophenesaccharin, and intermediate thiophene]

The synthesis started with a conjugate addition of a thiol to an unsaturated ester. The thiol is obviously the nucleophile and regioselectively chooses conjugate addition rather than attack on either ester group.

![Diagram of the reaction]

In the next step the diester is treated with base and a carbonyl condensation reaction occurs of the type you will meet in Chapter 26. There is a real question of regioselectivity here: an enolate could form next to either ester (as shown by the orange circles) and would then attack the other ester as a nucleophile. There is little to choose between these alternatives but the first was wanted and was selected by careful experimentation, although only in 50% yield. This was acceptable on a large scale as the product could be separated by crystallization, the most practical of all methods.

![Diagram of the second step in the reaction]

Reactions such as this—the attack of enolates on carbon electrophiles—form the subject of the next two chapters, where we will discuss in detail the mechanism of this type of reaction.

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book's Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Carbonyl groups show diverse reactivity

In earlier chapters we discussed the two types of reactivity displayed by the carbonyl group. We first described reactions that involve nucleophilic attack on the carbon of the carbonyl, and in Chapter 9 we showed you that these are among the best ways of making new C–C bonds. In this chapter we shall again be making new C–C bonds, but using electrophilic attack on carbonyl compounds: in other words, the carbonyl compound will be reacting as the nucleophile in the reaction. We introduced the nucleophilic forms of carbonyl compounds—enols and enolates—in Chapter 20. There you saw them reacting with electrophiles based on elements other than carbon, but they will also react well with carbon electrophiles provided the reaction is thoughtfully devised. Much of this chapter will concern that phrase, ‘thoughtfully devised’.

Thought is needed to ensure that the carbonyl compound exhibits the right sort of reactivity. In particular, the carbonyl compound must not act as an electrophile when it is intended to be a nucleophile. If it does, it may react with itself to give some sort of dimer—or even a polymer—rather than neatly attacking the desired electrophile. This chapter will consider ways of avoiding unwanted nucleophilic attack at the carbonyl C=O bond.

Fortunately, over the last four decades lots of thought has already gone into the problem of controlling the reactions of enolates with carbon electrophiles. This means that there are many excellent solutions to the problem: our task in this chapter is to help you understand which to use, and when to use them, in order to design useful reactions.

Some important considerations that affect all alkylations

The alkylations in this chapter will each consist of two steps. The first is the formation of a stabilized anion—usually (but not always) an enolate—by deprotonation with base.
The second is a substitution reaction: attack of the nucleophilic anion on an electrophilic alkyl halide. All the factors controlling SN1 and SN2 reactions, which we discussed at length in Chapter 15, are applicable here.

\[
\begin{align*}
\text{R1} & \quad \text{O} \\
\text{R1} & \quad \text{O} \\
\text{R2} & \quad \text{X} \\
\end{align*}
\]

In each case, we shall take one of two approaches to the choice of base.

- A strong base (with a conjugate acid of pK_a greater than that of the carbonyl compound) can be chosen to deprotonate the starting material completely. There is complete conversion of the starting material to the anion before addition of the electrophile, which is added in a subsequent step.
- Alternatively, a weaker base may be used in the presence of the electrophile. The weaker base will not deprotonate the starting material completely because its conjugate acid has a lower pK_a than the carbonyl compound: only a small amount of anion will be formed, but that small amount will react with the electrophile. More anion is formed as alkylation uses it up.

The second approach is easier practically (just mix the starting material, base, and electrophile), but works only if the base and the electrophile are compatible and don’t react together. With the first approach, which is practically more demanding, the electrophile and base never meet each other, so their compatibility is not a concern. We shall start with some compounds that avoid the problem of competing aldol reactions completely because they are not electrophilic enough to react with their own nucleophilic derivatives.

**Nitriles and nitroalkanes can be alkylated**

Problems that arise from the electrophilicity of the carbonyl group can be avoided by replacing C=O by functional groups that are much less electrophilic but are still able to stabilize an adjacent anion. We shall consider two examples, both of which you met in Chapter 20.

**Alkylation of nitriles**

The nitrile group, which mirrors the carbonyl group in general reactivity, is much less easily attacked by nucleophiles (N is less electronegative than O). The anion formed by deprotonating a nitrile using strong base will not react with other molecules of nitrile but will react very efficiently with alkyl halides. The slim, linear structure of the anions makes them good nucleophiles for SN2 reactions.

The nitrile does not have to be deprotonated completely for alkylation: with sodium hydroxide only a small amount of anion is formed. In the example below, such an anion reacts with propyl bromide to give 2-phenylpentanenitrile.

\[
\begin{align*}
\text{Ph} & \quad \text{CN} \\
\text{NaOH, BnEt}_3\text{N}^+\text{Cl}^- & \quad 35 \degree \text{C} \\
\text{Ph} & \quad \text{CN} \\
84\% \text{ yield} & \\
\end{align*}
\]
Nitrile-stabilized anions are so nucleophilic that they will react with alkyl halides rather well even when a crowded quaternary centre (a carbon bearing no H atoms) is being formed. In this example the strong base, sodium hydride, was used to deprotonate the branched nitrile completely and benzyl chloride was the electrophile. The greater reactivity of benzyl electrophiles compensates for the poorer leaving group. In DMF, the anion is particularly reactive because it is not solvated (as you saw in Chapter 12, p. 255, DMF solvates only the Na$^+$ cation).

![Structure](image)

The compatibility of sodium hydride with electrophiles means that, by adding two equivalents of base, alkylation can be encouraged to occur more than once. This dimethylated acid was required in the synthesis of a potential drug, and it was made in two steps from a nitrile.

![Structure](image)

Double alkylation with two equivalents of NaH in the presence of excess methyl iodide gave the methylated nitrile, which was hydrolysed to the acid. The monoalkylated product is not isolated—it goes on directly to be deprotonated and react with a second molecule of MeI.

![Structure](image)

With two nitrile groups, the delocalized anion is so stable that even a weak, neutral amine (triethylamine) is sufficiently basic to deprotonate the starting material. Here double alkylation again takes place, in 100% yield: note that the electrophile is good at SN2, and the dipolar aprotic solvent DMSO (like DMF) cannot solvate the ‘enolate’ anion, making it more reactive.

![Structure](image)

If the electrophile and the nitrile are in the same molecule and the spacing between them is appropriate, then intramolecular alkylation entails cyclization to form rings. The preparation of a cyclopropane is shown using sodium hydroxide as the base and chloride as a leaving group. With an intramolecular alkylation, the base and the electrophile necessarily have to be present together, but the cyclization is so fast that competing SN2 substitution of Cl$^-$ by HO$^-$ is not a problem.

![Structure](image)

Alkylation of nitroalkanes

The powerful electron-withdrawing nature of the nitro group means that deprotonation is possible even with quite weak bases. The pK$_a$ of MeNO$_2$ is 10, about the same as phenol.
Protons adjacent to a nitro group are in fact about as acidic as the same proton adjacent to two carbonyl groups; you can think of a nitro group as having double the electron-withdrawing power of a carbonyl group. Nitro-stabilized anions (‘nitronate anions’) react with carbon electrophiles and a wide variety of nitro-containing products can be produced. The anions are not, of course, enolates, but replacing the nitrogen with a carbon should help you to recognize the close similarity of these alkylations with the enolate alkylations described later.

Surprisingly few simple nitroalkanes are commercially available but more complex examples can be prepared readily by alkylation of the anions derived from nitromethane, nitroethane, and 2-nitropropane. For example, deprotonation of nitropropane with butyllithium followed by the addition of butyl iodide gives 3-nitroheptane in good yield. This reaction really does have to be done in two steps: BuLi is not compatible with alkyl halides!

 Nitroalkanes can be alkylated in a single step with hydroxide as a base: phase transfer conditions (see p. 585) keep the HO\(^{-}\) and the electrophile apart, preventing alcohol formation. The reaction below on the left works despite the quaternary carbon atom in the product. The reaction on the right gives a cyclic nitroalkane: now there really is no alternative: the base and electrophile must cohabit in the reaction mixture, so a weaker base such as potassium carbonate must be used—hydroxide or amines are no good here because they would undergo substitution reactions with the halide.

**Choice of electrophile for alkylation**

Enolate alkylations are S\(_2\)2 reactions (polar solvents, good charged nucleophile) so the electrophile needs to be S\(_2\)2-reactive if the alkylation is to succeed: primary and benzylic alkyl halides are among the best alkylating agents. More branched halides tend to prefer unwanted E2 elimination reactions because the anions themselves are basic. As a result, tertiary halides are useless for enolate alkylation. We shall see a way round this problem later in the chapter.

**Lithium enolates of carbonyl compounds**

The problem of self-condensation of carbonyl compounds (that is, enolate reacting with unenolized carbonyl) under basic conditions does not exist if there is absolutely no unenolized carbonyl compound present. One way to achieve this is to use a base sufficiently strong
(\(pK_a\) at least 3 or 4 units higher than \(pK_a\) of the carbonyl compound) to ensure that all of the starting carbonyl is converted into the corresponding enolate. This will work only if the resulting enolate is sufficiently stable to survive until the alkylation is complete. As you saw in Chapter 20, lithium enolates are stable, and are among the best enolate equivalents for use in alkylation reactions.

The best base for making lithium enolates is usually LDA, made from diisopropylamine (\(i-Pr_2NH\)) and BuLi. LDA will deprotonate virtually all ketones and esters that have an acidic proton to form the corresponding lithium enolates rapidly, completely, and irreversibly even at the low temperatures (about –78°C) required for some of these reactive species to survive. Deprotonation occurs through a cyclic mechanism, which is illustrated below for ketones and esters. The basic nitrogen anion removes the proton as the lithium is delivered to the forming oxyanion.

**Alkylation of lithium enolates**

The reaction of these lithium enolates with alkyl halides is one of the most important C–C bond-forming reactions in chemistry. Alkylation of lithium enolates works with both acyclic and cyclic ketones as well as with acyclic and cyclic esters (lactones). The general mechanism is shown below.

Typical experimental conditions for reactions of kinetic enolates involve formation of the enolate at very low temperature (–78°C) in THF. The strong base LDA is used to avoid self-condensation of the carbonyl compound but, while the enolate is forming, there is always a chance that self-condensation will occur. The lower the temperature, the slower the self-condensation reaction, and the fewer by-products there are. Once enolate formation is complete, the electrophile is added (still at –78°C: the lithium enolates may not be stable at higher temperatures). The reaction mixture is then usually allowed to warm up to room temperature to speed up the rate of the \(S_N2\) alkylation.

**Alkylation of ketones**

Precisely this sequence was used to methylate the ketone below, with LDA acting as base followed by methyl iodide as electrophile.
Their stability at low temperature means that lithium enolates are usually preferred, but sodium and potassium enolates can also be formed by abstraction of a proton by strong bases. The increased separation of the metal cation from the enolate anion with the larger alkali metals leads to more reactive but less stable enolates. Typical very strong Na and K bases include the hydrides (NaH, KH) or amide anions derived from ammonia (NaNH$_2$, KNH$_2$) or hexamethyldisilazane (NaHMDS, KHMDS). The instability of the enolates means that they are usually made and reacted in a single step, so the base and electrophile need to be compatible. Here are two examples of cyclohexanone alkylation: the high reactivity of the potassium enolate is demonstrated by the efficient tetramethylation with excess potassium hydride and methyl iodide.

**Alkylation of esters**

In Chapter 26 you will meet the reaction of an ester with its own enolate: the Claisen condensation. This reaction can be an irritating side reaction in the chemistry of lithium ester enolates when alkylation is desired, and again it can be avoided only if the ester is converted entirely to its enolate under conditions where the Claisen condensation is slow. A good way of stopping this happening is to add the ester to the solution of LDA (and not the LDA to the ester) so that there is never excess ester for the enolate to react with. Another successful tactic is to make the group R as large as possible to discourage attack at the carbonyl group. Tertiary butyl esters are particularly useful in this regard because they are readily made, t-butyli is extremely bulky, and yet they can still be hydrolysed in aqueous acid under mild conditions by the method discussed on p. 556. In this example, deprotonation of t-butyli acetate gives a lithium enolate that reacts with butyl iodide as the reaction mixture is warmed to room temperature.

**Alkylation of carboxylic acids**

The lithium enolates of carboxylic acids can be formed if two equivalents of base are used: one to make the carboxylate anion and one to make the enolate. It is not necessary to use a strong base to remove the first proton but, since the second deprotonation requires a strong base such as LDA, it is often convenient to use two equivalents of LDA to form the dianion. With carboxylic acids, even BuLi can be used on occasion because the intermediate lithium carboxylate is much less electrophilic than an aldehyde or a ketone.

The next alkylation of an acid enolate is of a carbamate-protected amino acid, glycine. As you saw in Chapter 23, carbamate protecting groups are stable to basic reaction conditions. Three acidic protons are removed by LDA, but alkylation takes place only at carbon—the site of the last proton to be removed. Alkylation gets rid of one of the negative charges, so that, if the molecule gets a choice, it alkylates to get rid of the least stable anion, keeping the two more
stabilized charges. A good alternative to using the dianion is to alkylate the ester or nitrile and then hydrolyse to the acid.

\[
\begin{align*}
&\text{NHBoc} & \text{OH} & \text{t-BuO} & \text{N} & \text{Li} & \text{OLi} & \text{O} & \text{t-BuO} & \text{N} & \text{Li} & \text{OLi} & \text{O} & \text{Ph} & \text{Br} & \text{Ph} & \text{Li} & \text{BocHN} & \text{OH} \\
&\text{enolate trianion}
\end{align*}
\]

- Alkylation of ketones, esters, and carboxylic acids is best carried out using the lithium enolates.

**Why do enolates alkylate on carbon?**

Enolates have two nucleophilic sites: the carbon and the oxygen atoms. On p. 453 we showed that:

- carbon has the greater coefficient in the HOMO, and is the softer nucleophilic site
- oxygen carries the greater total charge and is the harder nucleophilic site. In Chapter 20 you saw that hard electrophiles prefer to react at oxygen—that is why it is possible to make silyl enol ethers, for example. Some carbon electrophiles with very good leaving groups also tend to react on oxygen, but soft electrophiles such as alkyl halides react at carbon, and you will see only this type of electrophile in this chapter.

In general:

- hard electrophiles, particularly alkyl sulfates and sulfonates (mesylates, tosylates), tend to react at oxygen
- soft electrophiles, particularly alkyl halides (I > Br > Cl), react at carbon
- polar aprotic solvents (DMSO, DMF) promote O-alkylation by separating the enolate anions from each other and the counterion (making the bond more polar and increasing the charge at O) while ethereal solvents (THF, DME) promote C-alkylation
- larger alkali metals (Cs > K > Na > Li) give more separated ion pairs (more polar bonds), which are harder and react more at oxygen.

Hard electrophiles react at O

\[
\begin{align*}
&\text{O} & \text{Me} & \text{X} & \text{R} & \text{O} & \text{Me} \\
&\text{X} = \text{OMs}, \text{OSO}_2\text{OMe}, \text{O} & \text{OMe}_2
\end{align*}
\]

Soft electrophiles react at C

\[
\begin{align*}
&\text{O} & \text{Me} & \text{X} & \text{R} & \text{O} & \text{Me} \\
&\text{X} = \text{I}, \text{Br}, \text{Cl}
\end{align*}
\]

**Alkylation of aldehydes: avoid LDA**

Aldehydes are so electrophilic that, even with LDA at –78°C, the rate at which the deprotonation takes place is not fast enough to outpace reactions between the forming lithium enolate and still-to-be-deprotonated aldehyde remaining in the mixture. Direct addition of the base to the carbonyl group of electrophilic aldehydes can also pose a problem.

Avoid using lithium enolates of aldehydes.
Using specific enol equivalents to alkylate aldehydes and ketones

These side reactions mean that aldehyde enolates are not generally useful reactive intermediates. Instead, there are a number of aldehyde enol and enolate equivalents in which the aldehyde is present only in masked form during the enolization and alkylation step. The three most important of these specific enol equivalents are:

- enamines
- silyl enol ethers
- aza-enolates derived from imines.

You met these enolate equivalents briefly in Chapter 20, and we shall discuss how to use them to alkylate aldehydes shortly. All three types of specific enol equivalent are useful not just with aldehydes, but with ketones as well, and we shall introduce each class with examples for both types of carbonyl compound.

Enamines are alkylated by reactive electrophiles

Enamines are formed when aldehydes or ketones react with secondary amines. The mechanism is given in Chapter 11. The mechanism below shows how they react with alkylating agents to form new carbon–carbon bonds: the enamine here is the one derived from cyclohexanone and pyrrolidine. The product is at first not a carbonyl compound: it’s an iminium ion or an enamine (depending on whether an appropriate proton can be lost). But a mild acidic hydrolysis converts the iminium ion or enamine into the corresponding alkylated carbonyl compound.

The overall process, from carbonyl compound to carbonyl compound, amounts to an enolate alkylation, but no strong base or enolates are involved so there is no danger of self-condensation. The example below shows two specific examples of cyclohexanone alkylation using an enamine. Note the relatively high temperatures and long reaction times: enamines are among the most reactive of neutral nucleophiles, but they are still a lot less nucleophilic than enolates.
The choice of the secondary amine for formation of the enamine is not completely arbitrary even though it does not end up in the final alkylated product. Simple dialkyl amines can be used but cyclic amines such as pyrrolidine, piperidine, and morpholine are popular choices as the ring structure makes both the starting amine and the enamine more nucleophilic (the alkyl groups are ‘tied back’ and can’t get in the way). The higher boiling points of these amines allow the enamine to be formed by heating.

\( \alpha \)-Bromo carbonyl compounds are excellent electrophiles for \( S_2 \) reactions because of the rate-enhancing effect of the carbonyl group (Chapter 15). The protons between the halogen and the carbonyl are significantly more acidic than those adjacent to just a carbonyl group and there can be a serious risk of an enolate nucleophile acting as a base. Enamines are only very weakly basic, but react well as nucleophiles with \( \alpha \)-bromo carbonyl compounds, and so are a good choice.

The starting ketone here is unsymmetrical, so two enamines are possible. However, the formation of solely the less substituted enamine is typical. The outcome may be explained as the result of thermodynamic control: enamine formation is reversible so the less hindered enamine predominates. For the more substituted enamine, steric hindrance forces the enamine to lose planarity, and destabilizes it. The less substituted enamine, on the other hand, is rather more stable.

There is, however, a major problem with enamines: reaction at nitrogen. Less reactive alkylating agents—simple alkyl halides such as methyl iodide, for example—react to a significant degree at N rather than at C. The product is a quaternary ammonium salt, which hydrolyses back to the starting material and leads to low yields.
Enamines work best with reactive alkylating agents:
- allylic halides
- benzyl halides
- \( \alpha \)-halo carbonyl compounds.

That said, enamines are a good solution to the aldehyde enolate problem. Aldehydes form enamines very easily (one of the advantages of the electrophilic aldehyde) and these are immune to attack by nucleophiles—including, most importantly, the enamines themselves. Below are two examples of aldehyde alkylation using the enamine method. Both again use highly \( S_N2 \)-reactive electrophiles, and this is the main limitation of enamines.

Aza-enolates react with a wider range of \( S_N2 \)-reactive electrophiles

Enamines are the nitrogen analogues of enols and provide one solution to the aldehyde enolate problem when the electrophile is reactive. Imines are the corresponding nitrogen analogues of aldehydes and ketones: a little lateral thinking should therefore lead you to expect some useful reactivity from the nitrogen equivalents of enolates, known as aza-enolates. Aza-enolates are formed when imines are treated with LDA or other strong bases.

In basic or neutral solution, imines are less electrophilic than aldehydes: they react with organolithiums, but not with many weaker nucleophiles (they are more electrophilic in acid when they are protonated). So, as the aza-enolate forms, there is no danger at all of self-condensation.

Note that aza-enolates are formed from imines, which can be made only from primary amines. Enamines are made from aldehydes or ketones with secondary amines.
The overall sequence involves formation of the imine from the aldehyde that is to be alkylated—usually with a bulky primary amine such as t-butyl- or cyclohexylamine to discourage even further nucleophilic attack at the imine carbon. The imine is not usually isolated, but is deprotonated directly with LDA or a Grignard reagent (these do not add to imines, but they will deprotonate them to give magnesium aza-enolates).

\[
\text{aza-enolate formation} \\
\text{imine} \\
\text{aza-enolate}
\]

The resulting aza-enolate reacts like a ketone enolate with SN2-reactive alkylating agents—here, benzyl chloride—to form the new carbon–carbon bond and to re-form the imine. The alkylated imine is usually hydrolysed by the mild acidic work-up to give the alkylated aldehydes.

\[
\text{aza-enolate alkylation}
\]

In the next example, a lithium base (lithium diethylamide) is used to form the aza-enolate. The ease of imine cleavage in acid is demonstrated by the selective hydrolysis to the aldehyde without any effect on the acetal introduced by the alkylation step. The product is a mono-protected dialdehyde, which is difficult to prepare by other methods.

\[
\text{Aza-enolate alkylation is so successful that it has been extended from aldehydes, where it is essential, to ketones, where it can be a useful option. Cyclohexanones are among the most electrophilic simple ketones and can suffer from undesirable side reactions. The imine from cyclohexanone and cyclohexylamine can be deprotonated with LDA to give a lithium aza-enolate. In this example, iodomethylstannane was the alkylating agent, giving the tin-containing ketone after hydrolysis.}
\]

\[
\text{Aldehyde alkylation}
\]

Aza-enolates are the best general solution for alkylating aldehydes with most electrophiles. With very SN2-reactive alkylating agents, enamines can be used, and with very SN1-reactive alkylating agents, silyl enol ethers must be used.
Silyl enol ethers are alkylated by $S_n$-1-reactive electrophiles in the presence of Lewis acid

While the greater nucleophilicity of azaenolates means that they will react with a wider range of electrophiles, their basicity, like that of lithium enolates, means that they will not react with $S_n$-1-reactive electrophiles like tertiary alkyl halides. The solution to this problem is to use silyl enol ethers, which are less reactive and so require a more potent electrophile to initiate reaction. Carbocations will do, and they can be generated in situ by abstraction of a halide or other leaving group from a saturated carbon atom.

![Carbocation formation](image)

The best alkylating agents for silyl enol ethers are tertiary alkyl halides: they form stable carbocations in the presence of Lewis acids such as TiCl$_4$ or SnCl$_4$. Most fortunately, this is just the type of compound that is unsuitable for reaction with lithium enolates or enamines, as elimination results rather than alkylation: a nice piece of complementary selectivity. Below is an example: the alkylation of cyclopentanone with 2-chloro-2-methylbutane. The ketone was converted to the trimethylsilyl enol ether with triethylamine and trimethylsilylchloride: we discussed this step on p. 466 (Chapter 20). Titanium tetrachloride in dry dichloromethane promotes the alkylation step.

![Alkylation reaction](image)

**Summary: specific enol equivalents for aldehydes and ketones:**

- Lithium enolates can be used with $S_n$-2-reactive electrophiles, but cannot be made from aldehydes.
- Aza-enolates of aldehydes or ketones can be used with the same $S_n$-2-reactive electrophiles, but can be made from aldehydes.
- Enamines of aldehydes or ketones can be used with allylic, benzylic, or $\alpha$-halocarbonyl compounds.
- Silyl enol ethers of aldehydes or ketones can be used with $S_n$-1-reactive electrophiles such as allylic, benzylic, or tertiary alkyl halides.

**Alkylation of $\beta$-dicarbonyl compounds**

The presence of two, or even three, electron-withdrawing groups on a single carbon atom makes the remaining proton(s) sufficiently acidic ($pK_a$ 10–15) that even mild bases can lead to complete enolate formation. Bases of the strength of alkoxides ($pK_a$ of ROH = ca. 16) cannot deprotonate simple carbonyl compounds ($pK_a$ 20–25) completely, but readily generate anions stabilized by more than one electron-withdrawing group. The most important enolates of this type are those of 1,3-dicarbonyl (or $\beta$-dicarbonyl) compounds.

The resulting anions are alkylated very efficiently. This diketone is enolized even by potassium carbonate, and reacts with methyl iodide in good yield. Carbonate is such a bad nucleophile that the base and the electrophile can be added in a single step.
alkylation of a 1,3-dicarbonyl compound (or β-dicarbonyl compound)

Among the β-dicarboxyls two compounds stand out in importance—diethyl (or dimethyl) malonate and ethyl acetoacetate. You should make sure you remember their structures and trivial names.

With these two esters, the choice of base is important: nucleophilic addition can occur at the ester carbonyl, which could lead to transesterification (with alkoxides), hydrolysis (with hydroxide), or amide formation (with amide anions). The best choice is usually an alkoxide identical with the alkoxide component of the ester (that is, ethoxide for diethyl malonate, methoxide for dimethyl malonate). Alkoxides are basic enough to deprotonate between two carbonyl groups but, should substitution occur at C=O, there is no overall reaction.

In the first example below the electrophile is the allylic cyclopentenyl chloride, and the base is ethoxide in ethanol—most conveniently made by adding one equivalent of sodium metal to dry ethanol. The same base is used in the second alkylation, of ethyl acetoacetate with butyl bromide.

Various electron-withdrawing groups can be used in almost any combination with good results. In this example an ester and a nitrile cooperate to stabilize an anion. Nitriles are not quite as anion-stabilizing as carbonyl groups so this enolate requires a stronger base (sodium hydride) in an aprotic solvent (DMF) for success. The primary alkyl tosylate serves as the electrophile.

These doubly stabilized anions are alkylated so well that it is common to carry out an alkylation between two carbonyl groups, only to remove one of them at a later stage. This is made possible by the fact that carboxylic acids with a β-carbonyl group decarboxylate (lose carbon dioxide) on heating. The mechanism below shows how. After alkylation of the dicarbonyl compound the unwanted ester is first hydrolysed in base. Acidification and heating lead to

You met the stable enols of related compounds in Chapter 20.

If you need a reminder about the tosylate leaving group, turn back to p. 349.
decarboxylation via a six-membered cyclic transition state in which the acid proton is transferred to the carbonyl group as the key bond breaks, liberating a molecule of carbon dioxide. The initial product is the enol form of a carbonyl compound that rapidly tautomerizes to the more stable keto form—now with only one carbonyl group. Using this technique, β-keto-esters give ketones while malonate esters give simple carboxylic acids (both ester groups hydrolyse but only one can be lost by decarboxylation). Decarboxylation can occur only with a second carbonyl group appropriately placed β to the acid, because the decarboxylated product must be formed as an enol.

The alkylation of ethyl acetoacetate with butyl bromide on p. 596 was done with the expressed intention of decarboxylating the product to give hexan-2-one. These are the conditions for this decarboxylation: the heating step drives off the CO₂ by increasing the gearing on the entropy term (ΔS°) of the activation energy (two molecules are made from one).

Esters are much easier to work with than carboxylic acids, and a useful alternative procedure removes one ester group without having to hydrolyse the other. The malonate ester is heated in a polar aprotic solvent—usually DMSO—in the presence of sodium chloride and a little water. No acid or base is required and, apart from the high temperature, the conditions are fairly mild. The scheme below shows a dimethyl malonate alkylation (note that NaOMe is used with the dimethyl ester) and removal of the methyl ester.
The mechanism of decarboxylation is a rather unusual type of ester cleavage reaction. The bond that breaks is not the MeO–CO bond but instead the O–alkyl bond: the reaction is an SN2 substitution of carboxylate by Cl$^-$. 

Chloride is a poor nucleophile, but it is more reactive in DMSO, by which it cannot be solvated. And, as soon as the carboxylate is displaced, the high temperature encourages (entropy again) irreversible decarboxylation. The other by-product, MeCl, is also lost as a gas. The ‘decarboxylation’ (in fact, removal of a CO$_2$Me group, not CO$_2$) is known as the Krapcho decarboxylation. Because of the SN2 step, it works best with methyl malonate esters.

We have only looked at single alkylations of dicarbonyl compounds, but there are two acidic protons between the carbonyl groups and a second alkylation is usually possible. Excess of base and alkyl halide gives two alkylations in one step. More usefully, it is possible to introduce two different alkyl groups by using just one equivalent of base and alkyl halide in the first step.

With a dihaloalkane, rings can be formed by two sequential alkylation reactions: this is an important way of making cycloalkanecarboxylic acids. Even the usually more difficult (see Chapter 31) four-membered rings can be made in this way.

**Ketone alkylation poses a problem in regioselectivity**

Ketones are unique because they can have enolizable protons on both sides of the carbonyl group. Unless the ketone is symmetrical, or unless one side of the ketone happens to have no enolizable protons, two regioisomers of the enolate are possible and alkylation can occur on either side to give regioisomeric products. We need to be able to control which enolate is formed if ketone alkylations are to be useful.
**Thermodynamically controlled enolate formation**

Selective enolate formation is straightforward if the protons on one side of the ketone are significantly more acidic than those on the other. This is what you have just seen with ethyl acetoacetate: it is a ketone, but with weak bases ($pK_a$ of the conjugate acid < 18) it only ever enolizes on the side where the protons are acidified by the second electron-withdrawing group. If two new substituents are introduced, in the manner you have just seen, they will always both be joined to the same carbon atom. This is an example of thermodynamic control: only the more stable of the two possible enolates is formed.

This principle can be extended to ketones whose enolates have less dramatic differences in stability. Since enols and enolates are alkenes, the more substituents they carry the more stable they are. So, in principle, even additional alkyl groups can control enolate formation under thermodynamic control. Formation of the more stable enolate requires a mechanism for equilibration between the two enolates, and this must be proton transfer. If a proton source is available—and this can even be just excess ketone—an equilibrium mixture of the two enolates will form. The composition of this equilibrium mixture depends very much on the ketone but, with 2-phenylcyclohexanone, conjugation ensures that only one enolate forms. The base is potassium hydride: it’s strong, but small (and so has no difficulty removing the more hindered proton) and can be used under conditions that permit enolate equilibration.

The more substituted lithium enolates can also be formed from the more substituted silyl enol ethers by substitution at silicon—a reaction you met in Chapter 20. The value of this reaction now becomes clear because the usual way of making silyl enol ethers ($Me_3SiCl$, Et$_3N$) typically produces, from unsymmetrical ketones, the more substituted of the two possible ethers. Because the silyl enol ether (unlike the enolate itself) can be purified, fully regiochemically pure enolates can be formed in this way.
One possible explanation for the thermodynamic regioselectivity in the enol ether-forming step is related to our rationalization of the regioselectivity of bromination of ketones in acid on p. 464. Triethylamine is too weak a base ($pK_a$ of Et$_3$NH$^+$ is about 10) to deprotonate the starting carbonyl compound ($pK_a$ ca. 20), and the first stage of the reaction is probably an oxygen–silicon interaction. Loss of a proton now takes place through a cationic transition state, and this is stabilized rather more if the proton being lost is next to the methyl group: methyl groups stabilize partial cations just as they stabilize cations.

An alternative view is that reaction takes place through the enol: the Si–O bond is so strong that even neutral enols react with Me$_3$SiCl, on oxygen, of course. The predominant enol is the more substituted, leading to the more substituted silyl enol ether.

**Kinetic and thermodynamic control** were discussed in Chapters 12, 23, and 24, pp. 264, 546, and 581.

> To understand why less substituted C atoms have more acidic C–H bonds, think of base strengths: MeLi is a weaker base than t-BuLi, so the conjugate acid must be a stronger acid.

> There must never be more ketone in the mixture than base, or exchange of protons between ketone and enolate will lead to equilibration. Kinetic enolate formations with LDA must be done by adding the ketone to the LDA so that there is excess LDA present throughout the reaction.

**Kinetically controlled enolate formation**

LDA is too hindered to attack most carbonyl C=O bonds, so it attacks C–H instead. And, if there is a choice of C–H bonds, it will attack the least hindered possible. It will also prefer to attack more acidic C–H bonds, and C–H bonds on less substituted carbons are indeed more acidic. Furthermore, statistics helps, since a less substituted C atom has more protons to be removed (three versus two in this example) so, even if the rates were the same, the less substituted enolate would predominate.

These factors multiply to ensure that the enolate that forms will be the one with the fewer substituents—provided we now prevent equilibration of the enolate to the more stable, more substituted one. This means keeping the temperature low, typically -78°C, keeping the reaction time short, and using an excess of strong base to deprotonate irreversibly and ensure that there is no remaining ketone to act as a proton source. The enolate that we then get is the one that formed faster, under kinetic control—known as the ‘kinetic enolate’—and not necessarily the one that is more stable.
In general, this effect is sufficient to allow selective kinetic deprotonation of methyl ketones, that is, where the distinction is between Me and alkyl:

The same method works very well for 2-substituted cyclohexanones: the less substituted enolate forms. Even with 2-phenylcyclohexanone, which, as you have just seen, has a strong thermodynamic preference for the conjugated enolate, only the less substituted enolate forms.

2-Methylcyclohexanone can be regioselectively alkylated using LDA and benzyl bromide by this method.

### Dianions allow unusual regioselectivity in alkylations of methyl acetoacetate

In Chapter 23, we introduced the idea that the last-formed anion in any dianion or trianion is the most reactive. Methyl acetoacetate is usually alkylated on the central carbon atom because that is the site of the most stable enolate. But methyl acetoacetate dianion—formed by removing a second proton from the usual enolate with a very strong base (usually butyllithium)—reacts first on the less stable anion: the terminal methyl group. Protonation of the more stable enolate then leads to the product. Butyllithium can be used as a base because the anionic enolate intermediate is not electrophilic.

### Enones provide a solution to regioselectivity problems

Enolates can be made regiospecifically from, for example, silyl enol ethers or enol acetates just by treating them with an alkyllithium. These are both substitution reactions in which RLi
displaces the enolate: one is SN2(Si) and the other is attack at C=O. Provided there is no proton source, the enolate products have the same regiochemistry as their stable precursors, and single enolate regioisomers are formed.

\[
\begin{align*}
\text{silyl enol ether} & \quad \text{MeLi} \\
\text{lithium enolate} & \quad \text{SiMe}_4
\end{align*}
\]

But there is a problem: forming enol ethers or enol esters will usually itself require a regioselective enolization! There are two situations in which this method is nonetheless useful: when the more substituted lithium enolate (which is hard to make selectively otherwise) is required, and when a silyl enol ether can be formed by a method not involving deprotonation. These methods are what we shall now consider.

**Dissolving metal reduction of enones gives enolates regiospecifically**

In Chapter 23 you met the Birch reduction: the use of dissolving metals (K, Na, or Li in liquid ammonia, for example) to reduce aromatic rings and alkynes. The dissolving metal reduction of enones by lithium metal in liquid ammonia is similar to these reactions—the C=C bond of the enone is reduced, with the C=O bond remaining untouched. An alcohol is required as a proton source and, in total, two electrons and two protons are added in a stepwise manner, giving net addition of a molecule of hydrogen to the double bond.

The mechanism follows that described on p. 543: transfer of an electron forms a radical anion that is protonated by the alcohol to form a radical. A second electron transfer forms an anion that can undergo tautomerization to an enolate.

The enolate is stable to further reduction and protonation during the work-up will give a ketone. But reaction with an alkyl halide is more fruitful: because the enolate forms only where the double bond of the enone was, regioselective alkylation becomes possible.

\[
\begin{align*}
\text{enol acetate} & \quad \text{MeLi} \times 2 \\
\text{by-product} & \quad \text{MeLi}
\end{align*}
\]

The example below leads to the regioselective methylation of methylcyclohexanone. Only 2% of the minor regioisomer is formed.
The transfer of electrons is not susceptible to steric hindrance so substituted alkenes pose no problem. In the next example, the enolate reacts with allyl bromide to give a single diastereoisomer of the product (the allyl bromide attacks from the face opposite the methyl group). Naturally, only one regioisomer is formed as well.

**Conjugate addition to enones gives enolates regiospecifically**

Although we did not talk in detail about them at that time, you will recall from Chapter 22 that conjugate addition to enones generates first an enolate, which is usually protonated in the work-up. But, again, more fruitful things can be done with the enolate under the right conditions.

The simplest products are formed when \( \text{Nu} = \text{H} \), but this poses a problem of regioselectivity in the nucleophilic attack step: a nucleophilic hydride equivalent that selectively undergoes conjugate addition to the enone is required. This is usually achieved with extremely bulky hydride reagents such as lithium or potassium tri( sec-butyl)borohydride (often known by the trade names of L- or K-Selectride, respectively). In this example, K-Selectride reduces the enone to an enolate that is alkylated by methyl iodide to give a single regioisomer.

With organocopper reagents, conjugate addition introduces a new alkyl group and, if the resulting enolates are themselves alkylated, two new C–C bonds can be formed in a single step (a tandem reaction: one C–C bond formation rides behind another). In Chapter 22 we explained that the best organocuprate additions are those carried out in the presence of Me₃SiCl: the product of these reactions is a silyl enol ether, formed regioselectively (the ‘enol’ double bond is always on the side where the enone used to be).
The silyl enol ethers are too unreactive for direct alkylation by an alkyl halide, but by converting them to lithium enolates all the usual alkylation chemistry becomes possible. This type of reaction forms the key step in a synthesis of the natural product α-chamigrene. Conjugate addition of Me₂CuLi gives an enolate that is trapped with trimethylsilyl chloride. Methylthiophilum converts the resulting silyl enol ether into a lithium enolate by substitution at Si. The natural product has a spiro six-membered ring attached at the site of the enolate, and this is made by alkylating with a dibromide (you saw this done on p. 598). The first substitution is at the more reactive allylic bromide. A second enolization is needed to make the ring, but this can be done under equilibrating conditions because the required six-membered ring forms much faster than the unwanted eight-membered ring that would arise by attack on the other side of the ketone.

Among the most important of these tandem conjugate addition–alkylation reactions are those of cyclopentenones. With cyclopentenone itself, the trans diastereoisomer usually results because the alkylating agent approaches from the less hindered face of the enolate.

This is the sort of selectivity evident in the next example, which looks more complicated but is really just addition of an arylcopper reagent followed by alkylation (trans to the bulky Ar group) with an iodoester.

**Synthesis of prostaglandin E₂**

One of the most dramatic illustrations of the power of conjugate addition followed by alkylation is the short synthesis of the important biological molecule prostaglandin E₂ by Ryoji Noyori in Japan. The organocopper reagent and the alkylating agent contain all the functionality required for both side chains of the target in protected form. The required trans stereochemistry is assembled in the key step, which gives a 78% yield of a product requiring only removal of the silyl ether and ester protecting groups. The organometallic nucleophile was prepared from a vinyl iodide by halogen–metal exchange (Chapter 9). In the presence of copper iodide this vinyllithium adds to the cyclopentenone in a conjugate sense to give an intermediate enolate. Because in this case the starting enone already has a stereogenic centre, this step is also stereoselective: attack on the less hindered face (opposite the silyl ether) gives the trans product. The resulting enolate was alkylated with the allylic iodide containing the terminal ester: once again the trans product was formed. It is particularly vital that enolate equilibration is avoided in this reaction to prevent the inevitable E1cB elimination of the silyloxy group that would occur from the other enolate. Deprotection of the silyl groups using TBAF (Chapter 23) gives the product.
Using Michael acceptors as electrophiles

α,β-Unsaturated carbonyl compounds are, as you have just seen, an excellent source of regio-defined enolate equivalents. But they are also very effective electrophiles for reaction with enolates. In this last section we will consider conjugate addition reactions of enolates as an alternative way of making C–C bonds.

As with other conjugate additions, it is important in such reactions to choose conditions that prevent the nucleophile (here the enolate) attacking the C=O group directly. The same factors discussed in Chapter 22 govern the eventual outcome of the reaction. Thermodynamic control leads to conjugate addition but kinetic control leads to direct addition, so the key to successful conjugate addition is to ensure that direct addition to the carbonyl group is reversible. This enables the conjugate addition to compete and, as its product is more stable (it loses the weaker C=C π bond rather than the stronger C=O π), it eventually becomes the sole product.

One of the most important ways of making the direct addition reversible is to use a more stabilized enolate, since expulsion of the stable anion from the direct addition product is more favourable. An additional consequence of adding a second electron-withdrawing group such as CO₂Et is that the direct addition product is more hindered (and therefore less stable) than the conjugate addition product.

The nature of the carbonyl group in the α,β-unsaturated electrophile is also important as the more electrophilic carbonyl groups give more direct addition and the less electrophilic...
carbonyl groups (esters, amides) give more conjugate addition. Aldehydes and ketones can be pushed towards conjugate addition pathways by careful choice of enolate equivalent, while esters and amides are much less electrophilic at the carbonyl carbon and so are good substrates for conjugate addition.

- Conjugate addition is thermodynamically controlled; direct addition is kinetically controlled.

Stabilized enolates promote conjugate addition by:
- making direct addition (aldol reaction) more reversible
- making the direct addition (aldol) product more hindered.

Less reactive Michael acceptors promote conjugate addition by:
- making direct addition (aldol reaction) more reversible
- making the carbonyl group less electrophilic.

1,3-Dicarboxyl compounds undergo conjugate addition

β-Diesters (malonates and substituted derivatives, see p. 595) combine three useful features in conjugate addition reactions:
- they form stable enolate anions that undergo clean conjugate addition
- if required, one of the ester groups can be removed by hydrolysis and decarboxylation
- the remaining acid or ester is ideal for conversion into other functional groups.

Diethyl malonate adds to diethyl fumarate in a conjugate addition reaction promoted by sodium ethoxide in dry ethanol to give a tetraester. Diethyl fumarate is an excellent Michael acceptor because two ester groups withdraw electrons from the alkene. The mechanism involves deprotonation of the malonate, conjugate addition, and reprotonation of the product enolate by ethanol solvent. In this reaction two ester groups stabilize the enolate and two more promote conjugate addition.

The value of malonate esters is illustrated in this synthesis of a substituted cyclic anhydride by conjugate addition to ethyl crotonate, hydrolysis, and decarboxylation, followed by dehydration with acetic anhydride. This route is very general and could be used to make a range of anhydrides with different substituents simply by choosing an appropriate unsaturated ester.

If the nucleophile is sufficiently enolized under the reaction conditions then the enol itself is able to attack the unsaturated carbonyl compound. Enols are neutral and thus soft nucleo-
philes favouring conjugate attack. 1,3-Diketones are enolized to a significant extent (Chapter 20), and under acidic conditions conjugate addition proceeds very efficiently even though there can be absolutely no base present. In this example methyl vinyl ketone (butenone) reacts with a cyclic β-diketone promoted by acetic acid to form a quaternary centre.

$$\text{methyl vinyl ketone} + \text{AcOH/H}_2\text{O} \rightarrow \text{quaternary \ Centre}$$

1 h, 75 °C

The mechanism involves acid-catalysed conversion of the keto form of the cyclic β-diketone into the enol form, which is able to attack the protonated enone. The mechanistic detail is precisely analogous to the attack of an enolate; the only difference is that both reactants are protonated. The product is the enol form of the triketone, which rapidly tautomerizes to the more stable keto form.

$$\text{enolization}$$

The thermodynamic control of conjugate addition allows even enals that are very electrophilic at the carbonyl carbon to participate successfully. As you will see in the next chapter, an aldol reaction (direct addition to \( \text{C}=\text{O} \)) must be possible here, but it is reversible and 1,4-addition eventually wins out. Acrolein combines with this five-membered diketone under very mild conditions to give a quantitative yield of product.

$$\text{acrolein} + \text{H}_2\text{O} \rightarrow \text{product}$$

room temperature

Alkali metal (especially Na, K) enolates can undergo conjugate addition

The use of two anion-stabilizing groups is a sure way of promoting conjugate addition, but it is not essential. Simple lithium enolates are not ideal nucleophiles for thermodynamically controlled conjugate addition because lithium binds strongly to oxygen and so tends to stabilize the aldol product. Better results are often observed with sodium or potassium enolates, which are more dissociated. Potassium tert-butoxide is the ideal base for this example as it is hindered and so will not attack the ester but is basic enough to deprotonate the ketone to a certain extent.

Two enolates are possible but, under the equilibrating conditions, the more stable enolate is the one leading to the product with a quaternary carbon atom.

$$\text{enolate}$$

If the enolate carries a leaving group, we get a nice way of making a cyclopropane because the enolate formed by the conjugate addition can itself be alkylated.
Enamines are convenient stable enol equivalents for conjugate addition

If you want a more reliable way of doing a conjugate addition of an aldehyde or ketone without having a second anion-stabilizing group, you need some stable and relatively unreactive enol equivalent. On p. 591 you saw how enamines, particularly those derived from cyclic secondary amines, are useful in alkylation reactions. These neutral species are also perfect for conjugate addition as they are soft nucleophiles but are more reactive than enols and can be prepared quantitatively in advance. The reactivity of enamines is such that heating the reactants together, sometimes neat, is all that is required. Acid catalysis can also be used to catalyse the reaction at lower temperature.

\[
\text{enamine} + \text{ketone} \rightarrow \text{keto-acid product}
\]

1. mix neat
2. acid work-up

The mechanism is rather like enol addition. The differences are that the enamine is more nucleophilic because of the nitrogen atom and that the product is also an enamine, which can be converted into the corresponding carbonyl by mild acidic hydrolysis. This is usually performed during the work-up and so does not really constitute an extra step. The amine is washed out as the hydrochloride salt so isolation is straightforward. After conjugate addition the resulting enolate-iminium ion undergoes proton transfer rapidly to produce the more stable carbonyl-enamine tautomer. This is shown as an intramolecular process but it could just as easily be drawn with an external base and source of protons. The resulting enamine is then stable until aqueous acid is added at the end of the reaction. Hydrolysis occurs via the iminium ion to reveal the second carbonyl group and release the secondary amine.

In these two examples enamines from cyclohexanone formed with pyrrolidine and morpholine add in good yield to an \(\alpha,\beta\)-unsaturated carbonyl compound with an extra electron-withdrawing methylthio or phenylsulfonyl group.

Conjugate addition of silyl enol ethers leads to the silyl enol ether of the product

The best alternatives to enamines for conjugate addition of enols of aldehyde, ketone, and carboxylic acid derivatives are silyl enol ethers. These stable neutral nucleophiles react very well with Michael acceptors either spontaneously or with Lewis acid catalysts such as \(\text{TiCl}_4\) at low temperature. If the 1,5-dicarbonyl compound is required, then an aqueous work-up with either acid or base cleaves the silicon–oxygen bond in the product.
Addition of the silyl enol ether derived from acetophenone (PhCOME) to a disubstituted enone promoted by titanium tetrachloride is very rapid and gives the diketone product in good yield even though a quaternary carbon atom is created in the conjugate addition. This is a typical example of this very powerful class of conjugate addition reactions.

It is even possible to use a silyl enol ether to create a new C–C bond that joins two new quaternary centres. Silyl ketene acetals (the silyl enol ethers of esters) are more nucleophilic than ordinary silyl enol ethers, and in this example the silyl ketene acetal undergoes conjugate addition to an unsaturated ketone catalysed by the usual Lewis acid (TiCl₄) for such reactions.

**Ketene acetals**

Because enol ethers of esters have two identical OR groups joined to the same end of the same double bond, you will see them called ‘ketene acetals’ or, here, ‘silyl ketene acetals’. This is a reasonable description as you can imagine the carbonyl group of a ketene forming an acetal in the same way as an aldehyde. In fact, they cannot be made this way.

In these reactions, the electrophile coordinates to the TiCl₄ Lewis acid first, producing an activated enone that is attacked by the silylated nucleophile. It is difficult to determine at what stage the trimethylsilyl group moves from its original position and whether it is transferred intramolecularly to the product. In many cases the anion liberated from the Lewis acid (Cl⁻, RO⁻, Br⁻) is a good nucleophile for silicon so it is reasonable to assume that there is a free trimethylsilyl species (Me₃SiX) that captures the titanium enolate:

**A variety of electrophilic alkenes will accept enol(ate) nucleophiles**

The simplest and best Michael acceptors are those α,β-unsaturated carbonyl compounds with exposed unsaturated β carbon atoms, such as exo-methylene ketones, lactones, and vinyl ketones. However, their extreme reactivity can make them hard to handle (they polymerize readily), and in the next chapter (p. 621) you will meet a method that makes them in situ to circumvent these problems.
One trick to persuade a stubborn enolate to do conjugate rather than direct substitution is to add an extra anion-stabilizing substituent in the α position. The margin shows a selection of reagents that do this. In each case the extra group (CO$_2$Et, SPh, SOPh, SO$_2$Ph, SiMe$_3$, and Br) can be removed after the conjugate addition is complete.

Unsaturated esters are good Michael acceptors because they are not very electrophilic. Unsaturated amides are even less electrophilic and (provided they are tertiary and have no acidic NH protons) will even give conjugate addition products with lithium enolates.

Unsaturated esters are good Michael acceptors because they are not very electrophilic. Unsaturated amides are even less electrophilic and (provided they are tertiary and have no acidic NH protons) will even give conjugate addition products with lithium enolates.

The nitrile group is not as reactive towards direct attack by nucleophiles as its carbonyl cousins but is equally able to stabilize an adjacent negative charge. Alkenes conjugated with nitriles are thus activated towards nucleophilic attack without the complications of competing direct addition to the activating group.

With base, methyl benzyl ketone forms its more stable enolate, which undergoes smooth and rapid conjugate addition to acrylonitrile. Acrylonitrile is one of the best Michael acceptors for enolates.

The cyanide group can also act as an anion-stabilizing group in the nucleophile. In combination with an ester group, the enolizable proton is acidified to such an extent that potassium hydroxide can be used as base.

The simplest amino acid, glycine, would be an ideal starting material for the synthesis of more complicated amino acids but it does not easily form enols or enolates. By conversion to the methyl ester of its benzaldehyde imine, two electron-withdrawing groups are introduced to help stabilization of the enolate and conjugate addition of acrylonitrile is now possible. The base used was solid potassium carbonate. Simple hydrolysis of the alkylated product leads to the extended amino acid.

You saw on p. 606 how two ester groups in fumarate diesters encourage conjugate addition, but what if there are two different groups at the ends of the Michael acceptor? Then you must make a judgement as to which is more electron-withdrawing. One case is clear-cut. The nitro group is worth two carbonyl groups (p. 586) so that conjugate addition occurs β to the nitro group in this case.
Nitroalkanes are superb nucleophiles for conjugate addition

In this chapter so far you have seen that highly stabilized anions, such as those derived from β-dicarbonyl compounds, are particularly good at nucleophilic addition because their stability helps to reverse the unwanted alternative direct C=O addition (aldol) pathway, and facilitates proton transfer in the catalytic version of the reaction. The nitro group is so powerfully electron-withdrawing that just one is equivalent to two carbonyls in pK_a terms (p. 586). Thus if β-dicarbonyls are good for conjugate addition, you might expect nitroalkanes to undergo conjugate addition in just the same way. The good news is that they do, very well. The first stage is a base-catalysed conjugate addition.

The product enolate that is formed is much more basic than the anion of the nitro compound so it removes a proton from the nitro compound and provides another molecule of anion for the second round of the reaction.

The acidifying effect of the nitro group is so profound that very mild bases can be used to catalyse the reaction. This enables selective removal of the proton next to the nitro group and helps to avoid side reactions of the carbonyl component. Common examples of mild bases include amines, quaternary ammonium hydroxides, and fluorides. Even basic alumina (a largely inert powder) is sufficient to catalyse virtually quantitative addition of this benzylic nitroalkane to cyclohexenone at room temperature!

Anions of nitro compounds form quaternary centres with ease in additions to α,β-unsaturated mono- and diesters. The difference between the acidity of the protons next to a nitro group and those next to the esters in the products combined with the very mild basic conditions ensures that no unwanted side reactions occur.

The effectiveness of nitro compound conjugate addition makes it ideal for use in combination with other reactions in making several bonds in one pot. The next example combines conjugate addition and intramolecular conjugate addition to make a six-membered ring.
The base used for both steps is Cs₂CO₃. The large caesium cation forms fully ionic compounds so the uncomplexed carbonate ion can exert its full basicity. Deprotonation of the conjugate addition product next to the nitro group produces a second anion, which does an intra-molecular S₅N₂ displacement of iodide to form a six-membered ring.

The nitro group can be converted into other useful functional groups following conjugate addition. Reduction gives primary amines while hydrolysis reveals ketones. The hydrolysis is known as the Nef reaction and used to be achieved by formation of the nitro-stabilized anion with a base such as sodium hydroxide followed by hydrolysis with sulfuric acid. These conditions are rather unforgiving for many substrates (and products) so milder methods have been developed. One of these involves reaction of the nitro ‘enolate’ with ozone (ozonolysis) at low temperature rather than treatment with acid. Base-catalysed conjugate addition of nitropropane to methyl vinyl ketone occurred smoothly to give the nitroketone. Formation of the salt with sodium methoxide was followed by oxidative cleavage of the C≡N linkage with ozone. The product was a 1,4-diketone, which was isolated without further aldol reaction by this route.

The conjugate addition uses a base, benzyltrimethylammonium hydroxide, marketed as Triton B, which allows hydroxide to be soluble in organic solvents.

This is a good general method for the synthesis of 1,4-diketones, which can otherwise be difficult to make, and additional substituents are easily accommodated on the enone—a characteristic of conjugate addition.

The synthesis of a drug that acts on brain chemistry

We end this chapter with a simple commercial synthesis of a drug molecule—vivalan—described as a ‘dopaminergic antagonist’. It uses four reactions that you have met: conjugate addition of an enolate to acrylonitrile, reduction of CN to a primary amine, alkylation, and reduction of the amide. There is another reaction involved—cyclization to an amide—but this occurs spontaneously.

To conclude...

We have considered the reactions of enolates and their equivalents with alkyl halides and electrophilic alkenes. In the next chapter we move on to consider reactions we have deliber-
ately taken steps to avoid up to this point. We shall consider the same types of enolate equivalents reacting with carbonyl compounds themselves.

## Introduction

The last chapter was about reactions of enols and enolates with alkylating agents such as alkyl halides and α,β-unsaturated carbonyl compounds. We emphasized how important it was to avoid nucleophilic attack at the carbonyl group.

![alkylation of an enolate](image)

This chapter is about deliberately getting nucleophilic attack by enols and enolates on carbonyl groups of aldehydes or ketones (the aldol reaction in the first half of the chapter) or on acylating agents (the second half of the chapter).
The aldol reaction

The simplest enolizable aldehyde is acetaldehyde (ethanal, CH₃CHO). What happens if we add a small amount of base, say NaOH, to this aldehyde? Some of it will form the enolate ion.

$$\text{H}_2\text{O} \quad \text{H} \quad \text{H} \quad \text{O} \quad \text{H} \quad \text{O}$$

acetaldehyde enolate ion

$$\text{NaOH} \quad \text{HO}$$

Only a small amount of the nucleophilic enolate ion is formed: as we pointed out in Chapter 25, hydroxide is not basic enough to enolize an aldehyde completely. Each molecule of enolate is surrounded by molecules of the aldehyde that are not enolized and so still have the electrophilic carbonyl group intact. The enolate ion will attack one of these aldehydes to form an alkoxide ion, which will be protonated by the water molecule formed in the first step.

$$\text{H} \quad \text{O} \quad \text{O} \quad \text{H} \quad \text{O} \quad \text{H}$$

The product is an aldehyde with a hydroxy (ol) group and it has the trivial name aldol. The name aldol is given to the whole class of reactions between enolates (or enols) and carbonyl compounds even if in most cases the product is not a hydroxy-aldehyde at all. Notice that the base catalyst (hydroxide ion) is regenerated in the last step, so it is truly a catalyst.

This reaction is so important because of the carbon–carbon bond formed when the nucleophilic enolate attacks the electrophilic aldehyde. This bond is shown as a black bond in this version of the key step.

The reaction occurs with ketones as well. Acetone is a good example for us to use at the start of this chapter because it gives an important product, and as it is a symmetrical ketone, there can be no argument over which way it enolizes. Each step is the same as the aldol sequence with acetaldehyde, and the product is again a hydroxy-carbonyl compound, but this time a hydroxy-ketone.

$$\text{HO} \quad \text{O} \quad \text{H} \quad \text{O} \quad \text{OH} \quad \text{O} \quad \text{O} \quad \text{H}$$

The acetaldehyde reaction works well when one drop of dilute sodium hydroxide is added to acetaldehyde. The acetone reaction is best done with insoluble barium hydroxide, Ba(OH)₂. Both approaches keep the base concentration low. Without this precaution, the aldol products are not the compounds isolated from the reaction. With more base, further reactions occur because the aldol products dehydrate rather easily under the reaction conditions to give stable conjugated unsaturated carbonyl compounds.
These are elimination reactions, and you met them in Chapter 17, where the possible mechanisms are discussed. You cannot normally eliminate water from an alcohol in basic solution as hydroxide is a bad leaving group. It is the carbonyl group that allows elimination here: these are E1cB reactions, with a second enolization allowing the loss of OH⁻.

In the examples that follow you will see that the base-catalysed aldol reaction sometimes gives the aldol and sometimes the elimination product. The choice is partly based on conditions—the more vigorous the conditions (stronger base, higher temperature, longer time) the more likely elimination is to occur—and partly on the structure of the reagents.

The elimination is even easier in acid solution and acid-catalysed aldol reactions commonly give unsaturated products instead of aldols. In this simple example with a symmetrical cyclic ketone, the enone is formed in good yield in acid or base. We shall use the acid-catalysed reaction to illustrate the mechanism. First the ketone is enolized under acid catalysis as you saw in Chapter 20.

Then the aldol reaction takes place. Enols are less nucleophilic than enolates, and the reaction occurs because the electrophilic carbonyl component is protonated: the addition is acid-catalysed. An acid-catalysed aldol reaction takes place.

The aldol is a tertiary alcohol and would be likely to eliminate by an E1 mechanism in acid even without the carbonyl group. But the carbonyl ensures that only the stable conjugated enone is formed. Notice too that the dehydration is genuinely acid-catalysed as the acid reappears in the very last step.
None of these intermediates is detected or isolated in practice—simple treatment of the ketone with acid gives the enone in good yield. A base-catalysed reaction gives the same product via the aldol-E1cB elimination mechanism.

**Aldol reactions of unsymmetrical ketones**

If the ketone is blocked on one side so that it cannot enolize—in other words it has no protons on that side—only one aldol reaction is possible. Ketones of this type might bear a tertiary alkyl or an aryl substituent. *tert*-Butyl methyl ketone (3,3-dimethylbutan-2-one), for example, gives aldol reactions with various bases in 60–70% yield. Enolization cannot occur towards the *t*-butyl group and must occur towards the methyl group instead.

An especially interesting case of the blocked carbonyl compound is the lactone or cyclic ester. Open-chain esters do not give aldol reactions: they prefer a different reaction that is the subject of the second half of this chapter. But lactones are in some ways quite like ketones (the stretching frequencies of their C=O groups in the IR are similar, and unlike esters they react with NaBH₄ and give unsaturated carbonyl products under basic catalysis. Enolization is unambiguous because the ester oxygen atom blocks enolization on one side.

---

**Aldol condensations**

The term ‘condensation’ is often used for reactions like this. Condensations are reactions where two molecules combine with the loss of another small molecule—usually water. In this case, two ketones combine with the loss of water. This reaction is called an aldol condensation and chemists may say ‘two molecules of cyclopentanone condense together to give a conjugated enone’. You will also find the term ‘condensation’ used for all aldol reactions whether they occur with dehydration or not. The distinction is no longer important.
The enolate then attacks the carbonyl group of an unenolized lactone just as we have seen with aldehydes and ketones.

![aldol reaction of a lactone (cyclic ester)](image)

The last step is the familiar dehydration. As this reaction is being carried out in base we had better show the E1cB mechanism via the enolate of the aldol product.

![dehydration step](image)

You might have been surprised that the intermediate in the aldol step of this reaction did not decompose. This intermediate could be described as a tetrahedral intermediate in a nucleophilic substitution at a carbonyl group (Chapter 10). Why then does it not break down in the usual way?

The equilibrium does not affect the eventual product; it simply withdraws some of the material out of the productive reaction. We call this sort of equilibrium a parasitic equilibrium as it has no real life of its own—it just sucks the blood of the reaction.

The best leaving group is the alkoxide and the product is quite reasonable. But what is it to do now? The only reasonable next step is for it to close back up again. Because the lactone is a cyclic ester, the leaving group cannot escape—it must stay attached to the molecule. This reaction is reversible, but dehydration is effectively irreversible because it gives a stable conjugated product. Normal, acyclic esters are different: their alkoxide leaving groups can leave, and the result is a different sort of reaction, which you will meet later in this chapter.

**Cross-condensations**

So far we have considered only ‘self-condensations’—dimerization reactions of a single carbonyl compound. These form only a tiny fraction of known aldol reactions. Those that occur between two different carbonyl compounds, one acting as a nucleophile in its enol or enolate form, and the other as an electrophile, are called cross-condensations. They are more interesting than self-condensations, but working out what happens needs more thought. We shall start with an example that works well. The ketone PhCOMe reacts with 4-nitrobenzaldehyde in aqueous ethanol under NaOH catalysis to give a quantitative yield of an enone.

![cross-condensation](image)

The first step must be the formation of an enolate anion using NaOH as a base. Although both carbonyl compounds are unsymmetrical, there is only one site for enolization as there is only one set of α protons, on the methyl group of the ketone. The aldehyde has no α protons at all.
To get the observed product, the enolate obviously attacks the aldehyde to give an aldol, which then dehydrates by the E1cB mechanism.

Now, in this step there was a choice. The enolate could have attacked another molecule of unenolized ketone. It didn’t, because ketones are less reactive than aldehydes (Chapter 6). In this case the aldehyde has an electron-withdrawing nitro substituent too, making it even more reactive. The enolate selects the better electrophile—that is, the aldehyde.

In other cases the balance may shift towards self-condensation. You might think that a crossed aldol reaction between acetaldehyde and benzophenone (diphenylketone Ph₂C=O) should work well.

After all, only the aldehyde can enolize and the enolate could attack the ketone.

But it won’t work. The ketone is very hindered and very conjugated. It is less electrophilic than a normal ketone and normal ketones are less electrophilic than aldehydes. Given a choice between attacking this ketone and attacking another (but unenolized) molecule of acetaldehyde, the enolate will choose the aldehyde every time. The reaction at the start of the chapter occurs, while the ketone is just a spectator.

**Successful crossed aldol reactions**

For this kind of crossed aldol reaction to work well we must have two conditions:

- One partner only must be capable of enolization.
- The other partner must be incapable of enolization and be more electrophilic than the enolizable partner.

Everyone remembers the first of these conditions, but it is easy to forget the second.
The Mannich reaction

At first sight formaldehyde (methanal, CH₂=O) seems the ideal electrophilic partner in a mixed aldol reaction. It cannot enolize. (Usually we are concerned with α hydrogen atoms in an aldehyde. Formaldehyde does not even have α carbon atoms.) And it is a super aldehyde. Aldehydes are more electrophilic than ketones because a hydrogen atom replaces one of the alkyl groups. Formaldehyde has two hydrogen atoms.

The trouble is that it is too reactive. It tends to react more than once and to give extra unwanted reactions as well. You might think that condensation between acetaldehyde and formaldehyde in base would be quite simple. The acetaldehyde alone can form an enolate, and this enolate will attack the more electrophilic carbonyl group, which is formaldehyde. In each reaction the only possible enolate attacks another molecule of formaldehyde. By now you have got the idea so we simply draw the next enolate and the structure of the third aldol.

This aldol is formed all right but it is not the final product of the reaction because, with an electrophile as powerful as formaldehyde, a second and a third aldol follow swiftly on the heels of the first.

Even this is not all. A fourth molecule of formaldehyde reacts with hydroxide ion and then reduces the third aldol. This reduction is known as the Cannizzaro reaction, and is described in the box below. The final product is the highly symmetrical ‘pentaerythritol’, C(CH₂OH)₄, with four CH₂OH groups joined in a tetrahedral array about the same carbon atom. The overall reaction uses four molecules of formaldehyde and can give a high yield (typically 80% with NaOH but as much as 90% with Mg(OH)₂ of the product.

The Cannizzaro reaction

As you know, aldehydes are generally at least partly hydrated in water. Hydration is catalysed by base, and we can represent the hydration step in base like this. The hydration product is an anion but, if the base is sufficiently strong (or concentrated) and as long as the aldehyde cannot be enolized, at least some will be present as a dianion.
The dianion is very unstable, and one way in which it can become much more stable is by behaving like a tetrahedral intermediate. Which is the best leaving group? Out of a choice of $O^2-$, $R^-$, and $H^-$, it’s $H^-$ that (if reluctantly) has to go. Hydride is, of course, too unstable to be released into solution but, if there is a suitable electrophile at hand (another molecule of aldehyde, for example), it is transferred to the electrophilic centre in a mechanism that bears some resemblance to a borohydride reduction.

A general solution to using formaldehyde in aldol reactions is to use the Mannich reaction. A typical example is shown in the margin: the reaction involves an enolizable aldehyde or ketone (here we use cyclohexanone), a secondary amine (here dimethylamine), the Mannich reaction formaldehyde as its aqueous solution, and catalytic $HCl$. The product is an amino-ketone from the addition of one molecule each of formaldehyde and the amine to the ketone.

The mechanism involves the preliminary formation of an imine salt from the amine and formaldehyde. The amine is nucleophilic and attacks the more electrophilic of the two carbonyl compounds available, which is, of course, formaldehyde. No acid is needed for this addition step, but acid-catalysed dehydration of the addition product gives the imine salt. In the normal Mannich reaction, this is just an intermediate but it is quite stable and the corresponding iodide is sold as Eschenmoser’s salt for use in Mannich reactions.

The electrophilic salt can now add to the enol (we are in acid solution) of the ketone to give the product of the reaction, an amine sometimes called a Mannich base.

By using this reaction, you can add one molecule of formaldehyde—and one only—to carbonyl compounds. You might, of course, reasonably object that the product is not actually an aldol product at all—indeed, if you wanted the aldol product, the Mannich reaction would be of little use to you. It nevertheless remains a very important reaction. First of all, it is a simple way to make amino-ketones and many drug molecules belong to this class.

Secondly, the Mannich products can be converted to enones. The most reliable method for making the enone is to alkylate the amine product of the Mannich reaction with $MeI$ and then treat the ammonium salt with base. Enolate ion formation leads to an $E1cB$ reaction rather like the dehydration of aldols, but with a better leaving group.

1. alkylate amine to give ammonium salt
2. treat with base: $E1cB$ elimination gives enone

Enones like this, with two hydrogen atoms at the end of the double bond, are called exomethylene compounds; they are very reactive and cannot easily be made or stored. They certainly cannot be made by aldol reactions with formaldehyde alone as we have seen. The solution
is to make the Mannich product, store that, and then to alkylate and eliminate only when the enone is needed. We have seen how useful this is in the Michael reaction in Chapter 25.

If the enone is wanted, any secondary amine will do as it does not end up in the molecule so the more convenient (less volatile and less smelly) cyclic amines, pyrrolidine, and piperidine, are often used. The very electrophilic enones with monosubstituted double bonds can be made in this way.

**Carbonyl compounds that are electrophilic but cannot enolize**

Good crossed aldol condensations require one component to enolize and act as a nucleophile and the other not to enolize and to act as the electrophile. Here follows a list of carbonyl substituents that prevent enolization and therefore force a carbonyl compound to take the role of the electrophilic partner. They are arranged roughly in order of reactivity with the most reactive towards nucleophilic attack by an enolate at the top. You do, of course, need two substituents to block enolization so typical compounds also appear in the list. Note that the last two entries—esters and amides—do not normally do aldol reactions with enolates, but they do react as acylating agents for enolates, as you will see later in this chapter.

**Compounds that can enolize but that are not electrophilic**

We can complement this type of selectivity with the opposite type. Are there any compounds that can enolize but that cannot function as electrophiles? No carbonyl compound can fill this role, but in Chapter 25 (p. 585) we met some ‘enolizable’ compounds that lacked carbonyl...
groups altogether. Most notable among these were the nitroalkanes. Deprotonation of nitroalkanes is not enolization nor is the product an enolate ion, but the whole thing is so similar to enolization that it makes sense to consider them together. You saw these anions, sometimes called nitronates, reacting with Michael acceptors in Chapter 25, and they also react well with aldehydes and ketones.

\[
\text{anion of nitromethane}
\]

This particular example, using cyclohexanone as the electrophile and nitromethane itself as the source of the ‘enolate’, works quite well with NaOH as the base in methanol solution to give the ‘aldol’ in reasonable yield. Once again this reaction involves choice. Either compound could enolize and, indeed, cyclohexanone reacts well with itself under essentially the same conditions.

\[
\begin{align*}
\text{CH}_3\text{NO}_2 & \quad \text{NaOH, MeOH} \\
\text{CH}_3\text{NO}_2 & \quad \text{NaOH, MeOH}
\end{align*}
\]

70% yield

Although cyclohexanone forms an enolate in the absence of nitromethane, when both ketone and nitroalkane are present, the base prefers to remove a proton from nitromethane. This is simply a question of pK\textsubscript{a} values. The pK\textsubscript{a} of a typical ketone is about 20 but that of nitromethane is 10. It is not even necessary to use as strong a base as NaOH (pK\textsubscript{a} of H\textsubscript{2}O = 15.7) to deprotonate nitromethane: an amine will do (pK\textsubscript{a} of R\textsubscript{2}NH\textsubscript{2} about 10) and secondary amines are often used.

The elimination step also occurs easily with nitro compounds and is difficult to prevent in reactions with aromatic aldehydes. Now you can see how the useful nitroalkene Michael acceptors in Chapter 22 were made.

\[

**Nitroalkenes as termite defence compounds**

Termites are social insects, and every species has its own ‘soldier’ termites that defend the nest. Soldier termites of the species *Prorhinotermes simplex* have huge heads from which they spray a toxic nitroalkene on their enemies.

\[
\begin{align*}
\text{defensive nitroalkene from termite soldiers}
\end{align*}
\]

Although this compound kills other insects and even other species of termites, it has no effect on the workers of the same species. To find out why this was so, Prestwich made some radioactive compound using the aldol reaction. First, the right aldehyde was made using an S\textsubscript{2} reaction with radioactive (\textsuperscript{14}C) cyanide ion on a tosylate followed by DIBAL reduction (Chapter 23) of the nitrile. The position of the \textsuperscript{14}C atom in each compound is shown in black.

\[
\begin{align*}
\text{R} & \quad \text{CN} \\
\text{Na} & \quad \text{DIBAL (i-Bu}_2\text{AlH)}
\end{align*}
\]
Then the aldol reaction was carried out with nitromethane and acetic anhydride in pyridine to give the nitro aldol. Elimination using sodium methoxide gave the defence compound (E-1-nitropentadec-1-ene) in 37% yield over the four steps.

If the worker termites were sprayed with the labelled compound, they were able to make it harmless by using an enzyme to reduce the nitroalkene to a nitroalkane. The still radioactive labelled nitroalkane could be re-isolated only from workers of the same species: other insects do not have the enzyme.

If an aldol reaction can be done with:
- only one enolizable component
- only one set of enolizable protons
- a carbonyl electrophile more reactive than the compound being enolized

then you are lucky and the crossed aldol method will work. But most aldol reactions aren’t like this: they are cross-condensations of aldehydes and ketones of various reactivities with several different enolizable protons. Crossedaldols on most pairs of carbonyl compounds lead to hopeless mixtures of products. In all cases that fail to meet these three criteria, a specific enol equivalent will be required: one component must be turned quantitatively into an enol equivalent, which will be reacted in a separate step with an electrophile. That is what the next section is about—and you will find that some of the methods have a lot in common with those we used for alkylating enolates in Chapter 25.

### Specific enol equivalents can be used to control aldol reactions

In Chapter 25 we saw that the alkylation of enolates was most simply controlled by preparing a specific enol equivalent from the carbonyl compound. The same approach is the most powerful of all the ways to control the aldol reaction. The table is a reminder of some of the most useful of these specific enol equivalents.

Specific enol equivalents are intermediates that still have the reactivity of enols or enolates but are stable enough to be prepared in good yield from the carbonyl compound. That was all we needed to know in Chapter 25. Now we know that a further threat is the reaction of the partly formed enol derivative with its unenolized parent and we should add that ‘no aldol reaction should occur during the preparation of the specific enol equivalent’.

Sensible choice of an appropriate specific enol equivalent will allow almost any aldol reaction to be performed successfully. The first two compounds in our list, the silyl enol ethers and the lithium enolates, have a particularly wide application and we should look first at the way these work. As the table suggests, silyl enol ethers are more like enols: they are non-basic and not very reactive. Lithium enolates are more like enolate anions: they are basic and reactive. Each is appropriate in different circumstances.

Lithium enolates in aldol reactions

Lithium enolates are usually made at low temperature in THF with a hindered lithium amide base (often LDA) and are stable under those conditions because of the strong O–Li bond. The formation of the enolate begins with Li–O bond formation before the removal of the proton from the position by the basic nitrogen atom.

This reaction happens very quickly—so quickly that the partly formed enolate does not have a chance to react with unenolized carbonyl compound before proton removal is complete.

Now, if a second carbonyl compound is added, it too complexes with the same lithium atom. This allows the aldol reaction to take place by a cyclic mechanism in the coordination sphere of the lithium atom. The aldol step itself is now a very favourable intramolecular reaction with a six-membered cyclic transition state. The product is initially the lithium alkoxide of the aldol, which gives the aldol on work-up.

This reaction works well even if the electrophilic partner is an enolizable aldehyde. In this example, an unsymmetrical ketone (blocked on one side by an aromatic ring) reacts as the enol partner in excellent yield with a very enolizable aldehyde. This is the first complete aldol reaction we have shown you using a specific enol equivalent: notice the important point that it is done in two steps:

- first, form the specific enol equivalent (here, the lithium enolate at low temperature)
- then add the electrophile.
Contrast the crossed aldols earlier in the chapter, where enolizable component, base, and electrophile were all mixed together in one step.

The next example is particularly impressive. The enol partner is a symmetrical ketone that is very hindered—there is only one hydrogen on either side. The electrophilic partner is a conjugated enal that is not enolizable but that might accept the nucleophile in a conjugate manner. In spite of these potential problems, the reaction goes in excellent yield.

You may wonder why we did not mention the stereochemistry of the first of these two products. Two new stereogenic centres are formed and the product is a mixture of diastereoisomers. In fact, both of these products were wanted for oxidation to the 1,3-diketone so the stereochemistry is irrelevant. This sequence shows that the aldol reaction can be used to make diketones too.

**Silyl enol ethers in aldol reactions**

The silyl enol ether can be prepared from its parent carbonyl compound by forming a small equilibrium concentration of enolate ion with weak base such as a tertiary amine and trapping the enolate with the very efficient oxygen electrophile Me₃SiCl. The silyl enol ether is stable enough to be isolated but is usually used immediately without storing.

You should look upon silyl enol ethers as rather reactive alkenes that combine with things like protons or bromine (Chapter 20), but do not react with aldehydes and ketones without catalysis: they are much less reactive than lithium enolates. As with alkylation (pp. 595 and 609), a Lewis acid catalyst is needed to get the aldol reaction to work, and a Ti(IV) compound such as TiCl₄ is popular.

The immediate product is actually the silyl ether of the aldol product but this is hydrolysed during work-up and the aldol is formed in good yield. The Lewis acid presumably bonds to the carbonyl oxygen atom of the electrophile.

Now the aldol reaction can occur: the positive charge on the titanium-complexed carbonyl oxygen atom makes the aldehyde reactive enough to be attacked even by the not very nucleophilic silyl enol ether. Chloride ion removes the silyl group and the titanium alkoxide...
This mechanism looks complicated, and it is. It is, in fact, not clear that the details of what we have written here are right: the titanium may well coordinate to both oxygens throughout the reaction, and some of the steps that we have represented separately probably happen simultaneously. However, all reasonable mechanisms will agree on two important points, which you must understand:

- Lewis acid is needed to get silyl enol ethers to react.
- The key step is an aldol reaction of the silyl enol ether with the Lewis-acid complexed electrophile.

The use of silyl enol ethers can be illustrated in a synthesis of manicone, a conjugated enone that ants use to leave a trail to a food source. It can be made by an aldol reaction between pentan-3-one (as the enol component) and 2-methylbutanal (as the electrophile). Both partners are enolizable so we shall need to form a specific enol equivalent from the ketone. The silyl enol ether works well. The aldol product will be a mixture of diastereoisomers but it eliminates to give a single compound.

The silyl enol ether is not isolated but is treated immediately with the aldehyde to give an excellent yield of the aldol. Dehydration in acid solution with toluenesulfonic acid (TsOH) gives the enone. You can see by the high yield in the aldol reaction that there is no significant self-condensation of either partner in the aldol reaction.

**Conjugated Wittig reagents as specific enol equivalents**

When the Wittig reaction was introduced (Chapter 11) we saw it simply as an alkene synthesis. Now if we look at one group of Wittig reagents, those derived from α-halo-carbonyl compounds, we can see that they behave as specific enol equivalents in making unsaturated carbonyl compounds.

You notice that we have drawn the intermediate ylid as an enolate just to emphasize that it is an enolate derivative: it can also be represented either as the ylid or as an equivalent C=P ‘phosphorane’ structure. If we look at the details of this sort of Wittig reaction, we shall see that ylid formation is like enolate anion formation (indeed it is enolate anion formation). Only a weak base is needed as the enolate is stabilized by the Ph₃P⁺ group as well.
The first step of the Wittig reaction proper is just like an aldol reaction as it consists of an enolate attacking an electrophilic carbonyl compound. But, instead of forming an ‘aldol’ product, this adduct goes on to form an unsaturated carbonyl compound directly.

The final stages follow the mechanism of the Wittig reaction you met in Chapter 11: you can now see them as a special case of dehydration of an ‘aldol’ made favourable by the formation of a phosphine oxide and an unsaturated carbonyl compound.

The conjugated ylides derived from aldehydes, ketones, and esters are all sufficiently stable to be commercially available as the ylids—one of the few examples of specific enolate equivalents that you can actually buy. The ylid corresponding to the enolate of acetaldehyde is a solid, m.p. 185–188°C, that reacts well with other aldehydes, even if they are enolizable.

The stability of the phosphonium-stabilized enolates also means that, although they react well with aldehydes, their reactions with ketones are often poor, and it is better in these cases to use phosphonate-stabilized enolates. Being anionic, rather than neutral, these enolates are more nucleophilic. If an ester enolate equivalent is being used, the best base is the alkoxide ion belonging to the ester; with a ketone enolate equivalent, use sodium hydride or an alkoxide.

These last reagents, where the anion is stabilized both by the adjacent carbonyl group (as an enolate) and by the adjacent P=O group, are just one of many examples of enolate anions stabilized by two electron-withdrawing groups. The most important members of this class, enolates of 1,3-dicarbonyl compounds, are the subject of the next section.

**Specific enol equivalents from 1,3-dicarbonyl compounds**

Although these are the oldest of the specific enol equivalents, they are still widely used because they need no special conditions—no low temperatures or strictly anhydrous solvents. The two most important are derived from malonic acid and ethyl acetoacetate.
Ethyl acetoacetate is partly enolized under normal conditions. So, you might ask, why doesn't it immediately react with itself by the aldol reaction? There are two aspects to the answer. First, the enol is very stable (see Chapter 20 for a full discussion) and, second, the carbonyl groups in the unenolized fraction of the sample are poorly electrophilic ester and ketone groups. The second carbonyl group of the enol is not electrophilic because of conjugation. When a normal carbonyl compound is treated with catalytic acid or base, we have a small proportion of reactive enol or enolate in the presence of large amounts of unenolized electrophile. Aldol reaction (self-condensation) occurs. With 1,3-dicarbonyl compounds we have a small proportion of not particularly reactive unenolized compound in the presence of large amounts of stable (and hence unreactive) enol. No aldol occurs.

If we want a crossed aldol reaction with a 1,3-dicarbonyl compound, we simply add a second, electrophilic carbonyl compound such as an aldehyde, along with a weak acid or base. Often a mixture of a secondary amine and a carboxylic acid is used.

Reaction no doubt occurs via the enolate ion generated by the amine while the carboxylic acid buffers the solution, neutralizing the product and preventing enolization of the aldehyde. The amine ($pK_a$ $R_2NH_2$ about 10) is a strong enough base to form a significant concentration of enolate from the 1,3-dicarbonyl compound ($pK_a$ about 13) but not strong enough to form the enolate from the aldehyde ($pK_a$ about 20). The formation of the enolate can be drawn from either tautomer of the malonate.

Now the enolate ion can attack the aldehyde in the usual way, and the buffer action of the acid produces the aldol product in the reaction mixture.

There is still one proton between the two carbonyl groups so enolate anion formation is again easy and dehydration follows to give the unsaturated product.
You may not want a product with both ester groups present, and we discussed in Chapter 25 how one of two 1,3-related ester groups may be removed by hydrolysis and decarboxylation. There is a simpler route with the aldol reaction. If, instead of the malonate diester, malonic acid is used, the decarboxylation occurs spontaneously during the reaction. The catalysts this time are usually a more basic mixture of piperidine and pyridine.

The reaction presumably uses the enolate anion of the monocarboxylate anion of malonic acid. Although this enolate is a dianion, its extensive delocalization and the intramolecular hydrogen bond make it really quite stable.

Next comes the aldol step. The dianion attacks the aldehyde, and after proton exchange the aldol is formed (still as the monocarboxylate in this basic solution).

Finally comes the decarboxylation step, which can occur though a cyclic mechanism (compare the decarboxylation mechanisms in Chapter 25). The decarboxylation could give either an $E$ or a $Z$ double bond depending on which acid group is lost as $\text{CO}_2$, but the transition state leading to the more stable $E$ product must be lower in energy since the product has $E$ geometry.

In the first part of this chapter we have looked at general solutions to the problem of controlling crossed aldol reactions. We’ll now turn to the detailed ways those solutions are used with different classes of enolizable compounds.
How to control aldol reactions of esters

Among the enolates of carboxylic acid derivatives, esters are the most widely used. Ester enolates cannot be used as such in crossed aldols with aldehydes because the aldehyde is both more enolizable and more electrophilic than the ester. It will just condense with itself and ignore the ester. The same is true for ketones. A specific enol equivalent for the ester will therefore be needed for a successful aldol reaction of an ester enolate.

Fortunately, because this is a classic problem, many solutions are available. You can use the lithium enolate or the silyl enol ether, usually made best via the lithium enolate.

A good example is the first step in a synthesis of the natural product himalchene by Oppolzer and Snowden. Even though the ester and the aldehyde are both crowded with substituents, the aldol reaction works well with the lithium enolate of the ester. The cyclic mechanism ensures that the enolate adds directly to the carbonyl group of the aldehyde and not in a conjugate (Michael) fashion.

Zinc enolates, made from the bromoesters, are a good alternative to lithium enolates of esters. The mechanism for zinc enolate formation should remind you of the formation of a Grignard reagent.

There is no danger of self-condensation with zinc enolates as they do not react with esters. But they do react cleanly with aldehydes and ketones to give aldols on work-up. You will appreciate that the use of zinc enolates is therefore special to esters: you cannot make a zinc enolate from a 2-bromoaldehyde or an α-bromo ketone as then you would get self-condensation.
Ester enolate equivalents

For aldol reactions with an ester enolate equivalent, use:

- lithium enolates or
- silyl enol ethers or
- zinc enolates.

\[
R^1\text{CO}_2\text{Et} \xrightarrow{\text{OLi}} \xrightarrow{\text{OSiMe}_3} \xrightarrow{\text{OZnBr}}
\]

lithium enolate  silyl enol ether  zinc enolate

How to control aldol reactions of aldehydes

Aldehydes enolize very readily but also self-condense rather easily. Lithium enolates of aldehydes can’t be made cleanly because the self-condensation reaction happens even at –78 °C and is as fast as the enolization by LDA. Silyl enol ethers are a much better choice. They clearly must not be made via the lithium enolate, and amine bases are usually used. As each molecule of enolate is produced in the equilibrium, it is efficiently trapped by the silylating agent.

These silyl enol ethers are probably the best way of carrying out crossed aldol reactions with an aldehyde as the nucleophilic (enol or enolate) partner. An example is the reaction of the enol of the not very enolizable isobutyraldehyde with the very enolizable 3-phenylpropanal. Mixing the two aldehydes and adding base would of course lead to an orgy of self-condensation and cross-couplings.

Preliminary formation of the silyl enol ether from either aldehyde, in the absence of the other, would be trouble-free as Me_3SiCl captures the enolate faster than self-condensation occurs. Here we need the silyl enol ether from isobutyraldehyde. The other aldehyde is now added along with the necessary Lewis acid, here TiCl_4. The mechanism described on p. 627 gives the aldol after work-up in an excellent 95% yield. No more than 5% of other reactions can have occurred.

Other useful specific enol equivalents of aldehydes and ketones are enamines and aza-enolates, which you saw in use in alkylation reactions in Chapter 25. Aza-enolates—the lithium enolates of imines—derived from aldehydes are also useful in aldol reactions. Cyclohexylamine gives a reasonably stable imine even with acetaldehyde and this can be isolated and lithiated with LDA to give the aza-enolate. The mechanism is similar to the formation of lithium enolates and the lithium atom binds the nitrogen atom of the aza-enolate, just as it binds the oxygen atom of an enolate.
The aza-enolate reacts cleanly with other aldehydes or ketones to give aldol products. Even the most challenging of cross-couplings—attack on another similar enolizable aldehyde—occurs in good yield.

The initial product is a new imine, which is easily hydrolysed during acidic aqueous work-up. The alkoxide is protonated, the imine hydrolysed, and finally the aldol is dehydrated to give the enal—65% overall yield in this case.

The key to the success of the aza-enolates is that the imine is first formed from the aldehyde with the primary amine, a relatively weak base, and under these conditions imine formation is faster than self-condensation. Only after the imine is formed is LDA added when self-condensation cannot occur simply because no aldehyde is left.

Except in certain cases (and you will meet some of these in Chapter 41) enamines are not generally used in aldol condensations, partly because they are not reactive enough, but mainly because they are too much in equilibrium with the carbonyl compound itself and exchange would lead to self-condensation and the wrong cross-couplings. You will see later that enamines come into their own when we want to acylate enols with the much more reactive acid chlorides.

● **Aldehyde enolate equivalents**

For crossed aldol reactions with an aldehyde as the enol partner, use:
- silyl enol ethers or
- aza-enolates.

For acylation of aldehyde enolates (see later), use silyl enol ethers or enamines.
How to control aldol reactions of ketones

The enolization of ketones, unless they are symmetrical, poses a special problem. Not only do we need to prevent them self-condensing (although this is less of a problem than with aldehydes), but we also need to control which side of the carbonyl group the ketone enolizes. In this section we shall introduce aldol reactions with unsymmetrical ketones where one of two possible enols or enolates must be made.

Making the less substituted enolate equivalent: kinetic enolates

Treatment of methyl ketones with LDA usually gives only the lithium enolate on the methyl side. This is the enolate that forms the fastest and is therefore known as the kinetic enolate. It is formed faster because:

- the protons on the methyl group are more acidic
- there are three of them as against two on the other side, and
- there is steric hindrance to attack by LDA on the other side of the carbonyl group.

A simple example from the first report of this reaction by Gilbert Stork and his group in 1974 is the condensation of pentan-2-one with butanal to give the aldol and then the enone oct-4-en-3-one by acid-catalysed dehydration. The yields may seem disappointing, but this was the first time anyone had carried out a crossed aldol reaction like this with an unsymmetrical ketone and an enolizable aldehyde and got just one aldol product in any reasonable yield at all.

An uncontrolled ketone aldol

A more typical result from the days before specific enol condensation between butanone and butanal with equivalents had been invented is this attempted crossed catalytic base. Two products were isolated in low yield.

Product A is from the enolate of the more substituted side of the ketone reacting with the aldehyde, and product B is just the self-condensation product from the aldehyde.

These kinetic lithium enolates are stable in THF at −78°C for a short time but can be preserved at room temperature in the form of their silyl ethers.
Aldol reactions can be carried out with either the lithium enolate or the silyl enol ether. As an example we shall use the synthesis of a component of the flavour of ginger. The hotness of ginger comes from ‘gingerol’—the ‘pungent principle’ of ginger. Gingerol is a 3-hydroxyketone, so we might consider using an aldol reaction to make it. We shall need the enol (or enolate) on the methyl side of an unsymmetrical ketone to react with a simple aldehyde (pentanal) as the electrophilic partner in the aldol reaction. Pentanal is an enolizable aldehyde, so we must stop it enolizing. The diagram summarizes the proposed aldol reaction.

We might consider using the lithium enolate or the silyl enol ether. As we need the kinetic enolate (the enolate formed on the less substituted side of the ketone), we shall be using the lithium enolate to make the silyl enol ether, so it would make sense to try that first. There is another problem too. The ketone has a free OH group on the far side of the ring that will interfere with the reaction. We must protect that first as an ordinary silyl ether (not a silyl enol ether).

Now we can make the kinetic lithium enolate with a hindered lithium amide base. In fact, the one chosen here was even more hindered than LDA as it has two Me,Si groups on the nitrogen atom.

**Lithium hexamethyldisilazide**

Lithium hexamethyldisilazide (LiHMDS) is a little more hindered than LDA and a little less basic. It is made by deprotonating hexamethyldisilazane with BuLi.

An aldol reaction with this lithium enolate on pentanal was successful and the protecting group (the silyl ether) was conveniently hydrolysed during work-up to give gingerol itself. However, the yield was only 57%. When the silyl enol ether was used with TiCl₄ as the Lewis
acid catalyst, the yield jumped to 92%. This is one of the many successful uses of this style of aldol reaction by Mukaiyama, the inventor of the method.

Making the more substituted enolate equivalent: thermodynamic enolates

Being an alkene, an enol or enolate is more stable if it has more substituents. So the way to make the more substituted enolate equivalent is to make it under conditions where the two enolates can interconvert: equilibration will give the more stable form. You have seen in Chapter 25 (p. 599) how the silyl enol ether on the more substituted side of a ketone can be made by treating the ketone with Me₃SiCl and a weak base, but these thermodynamic silyl enol ethers have been little used in aldol reactions. One successful example is the thermodynamic silyl enol ether of 1-phenylpropan-2-one: enolization on the conjugated side is overwhelmingly favoured thermodynamically. The aldol reaction with a 2-ketoaldehyde goes exclusively for the more reactive aldehyde group.

This concludes our general survey of specific enolates in the aldol reaction. Later you will see many of the same reagents used in acylation at carbon. We are left with some reactions that are particularly easy to do.

Intramolecular aldol reactions

Now for something easy. When an aldol reaction can form a five- or six-membered ring, you need no longer worry about specific enols or anything like that. Equilibrium methods with weak acids or bases are quite enough to give the cyclic product by an intramolecular aldol reaction because intramolecular reactions are faster than intermolecular ones. We shall illustrate intramolecular reactions by looking at the cyclization of a series of diketones of increasing complexity, starting with one that can form four equivalent enols: cyclodeca-1,6-dione.

It doesn't matter where enolization occurs because the same enol is formed. And once the enol is formed, there is only one thing it can reasonably do: attack the other ketone to form a stable five-membered ring. It also gives a reasonably stable seven-membered ring, but that is by the way. In weak acid or base, only a small proportion of carbonyl groups will be enolized, so the chance of two being in the same molecule is very low. No intermolecular condensation is found and the yield of the bicyclic enone from the intramolecular reaction is almost 100% (96% with Na₂CO₃).
This may look like a long stretch for the enol to reach across the ten-membered ring to reach the other ketone, but the conformational drawing in the margin shows just how close they can be. You should compare this conformation with that of a decalin (Chapter 16).

The key point to remember with intramolecular aldols is this:

- Intramolecular reactions giving five- or six-membered rings are preferred to those giving strained three- or four-membered rings on the one hand or medium rings (eight- to thirteen-membered) on the other.

Acid-catalysed cyclization of the symmetrical diketone nona-2,8-dione could give two enols.

One enol can cyclize through an eight-membered cyclic transition state and the other through a six-membered one. In each case the product would first be formed as an aldol but would dehydrate to the cyclic enone having the same ring size as the transition state. In practice, only the less strained six-membered ring is formed and the enone can be isolated in 85% yield.

Most diketones lack symmetry, and will potentially have four different sites for enolization. Consider what might happen when this diketone is treated with KOH. There are four different places where an enolate anion might be formed as there are four different carbon atoms. There are also two different electrophilic carbonyl groups so that there are many possibilities for inter- and intramolecular condensation. Yet only one product is formed, in 90% yield.
We can deduce the mechanism of the reaction simply from the structure of the product by working backwards. The double bond is formed from an aldol whose structure we can predict and hence we can see which enolate anion was formed and which ketone acted as the electrophilic partner.

Must we argue that this one enolate is more easily formed than the other three? No, of course not. There is little difference between all four enolates and almost no difference between the three enolates from CH₂ groups. We can argue that this is the only aldol reaction that leads to a stable conjugated enone in a stable six-membered ring. This must be the mechanism; the others are just too slow to compete. Protonation and dehydration follow as usual.

Now try some of the alternatives in which the same ketone forms an enolate on the other side. These reactions give unstable four-membered rings or bridged bicyclic systems that would revert to the enolate. Providing the reaction is done under equilibrating conditions, the whole process would go into reverse back to the original diketone and the observed (six-membered ring) cyclization would eventually predominate. The key point about the bridged compound in the margin is that dehydration is impossible. No enolate can form at the bridgehead because bridgehead carbons cannot be planar (Chapter 17, p. 389) and the enone product cannot exist for the same reason: the carbons marked (●) in the brown structure would all have to lie in the same plane. The aldol has a perfectly acceptable conformation but that elimination is impossible. The aldol product remains in equilibrium with the alternative aldol products, but only one elimination is possible—and that is irreversible, so eventually all the material ends up as the one enone.

The Robinson annelation

One of the most important applications of the intramolecular aldol reaction is a ring synthesis (annelation or annulation) that takes place in two steps, both involving enols. The compound made by Robinson in the first example is a bicyclic diketone that contains the basic structure of rings A and B of the steroids. The bonds made in the two steps are marked.
Only a weak base is needed to form the stable enolate of the 1,3-diketone and this does
conjugate addition onto the enone (Chapter 25). The intermediate triketo may be isolated
but often isn’t.

The second stage starts with the intramolecular aldol reaction. You should be able to see
that the alternatives to a six-membered ring are a four-membered ring and bridged products.
The hydroxy-ketone, which happens to have the cis stereochemistry, can also be isolated but
eliminates by the E1cB mechanism to complete the aldol sequence.

Other ways to carry out this same reaction are to use a secondary amine as the weak base. This
gives an excellent yield of the hydroxyketone that can be converted into the enone with acid.

In this sequence the new ring is built onto the side of an old ring but this is not necessary.
Any combination of an easily enolizable compound and an enone may give a Robinson
annelation product. A simple example combines a non-enolizable enone with ethyl acetacetate to give an excellent yield of a cyclohexenone. As these compounds are so robust a
stronger base can be used.

**The Darzens reaction**

Tandem reactions, in which a second enolate reaction follows on from the first, can allow us
to make cyclopropanes (see Chapter 25, p. 586), by conjugate addition followed by C-alkylation,
or epoxides, by aldol addition followed by O-alkylation. This epoxide was used in the synthesis of the drug Darusentan.
The formation of epoxides in this way complements their formation from alkenes with m-CPBA because it involves construction of a C–C bond. Epoxide formation from α-halogenated carbonyl compounds is known as the Darzens reaction.

**Acetylation at carbon**

**Introduction: the Claisen ester condensation and the aldol reaction compared**

We began this chapter with the treatment of acetaldehyde with base. This led initially to the formation of an enolate anion and then to the aldol reaction. We are going to start this section by looking at what happens if you just treat ethyl acetate with base. To start with, there is hardly any difference. We shall use ethoxide as base rather than hydroxide as hydroxide would hydrolyse the ester, but otherwise the first steps are very similar. Here they are, side by side.

The next step in both cases is nucleophilic attack by the enolate ion on unenolized carbonyl compound. The concentration of enolate is low and each enolate ion is surrounded by unenolized aldehyde or ester molecules, so this reaction is to be expected. Here is that step, again shown for both aldehyde and ester.

Only now does something different happen. The aldehyde dimer simply captures a proton from the solvent to give an aldol product. The ‘aldol’ from the ester (not, in fact, an aldol at all) has a leaving group, EtO−, instead of a hydrogen atom and is actually the tetrahedral intermediate in a nucleophilic substitution at the carbonyl group. Compare the two different steps again.

Even though the last step is different, the two products are quite similar. Both are dimers of the original two-carbon chain and both have carbonyl groups at the end of the chain and oxygen substituents at position three. The two reactions obviously belong to the same family but are usually given different names. The ester reaction is sometimes known as the Claisen ester condensation and sometimes as the Claisen–Schmidt reaction. More important than remembering the name is being familiar with the reaction and its mechanism.
This is another of those reactions where the base is not strong enough to transform the ester entirely into the enolate. Only a small equilibrium concentration is produced, which reacts with the ester electrophile. The by-product from the reaction is ethoxide ion and so it looks at first sight as though we get our catalyst back again—the aldol, if you remember, is catalytic in base. But not the Claisen reaction. The second step of the reaction is also really an equilibrium, and the reaction works only because the product can be irreversibly deprotonated by the ethoxide by-product, consuming ethoxide in the process. You recall that the aldol reaction often works best when there is an extra driving force to push it across—dehydration to an enone, for example. Similarly, the ester dimerization works best when the product reacts with the ethoxide ion to give a stable enolate ion.

The point is that the base used, ethoxide ion EtO−, is too weak (EtOH has a pKₐ of about 16) to remove the proton completely from ethyl acetate (pKₐ about 25), but is strong enough to remove a proton from the acetoacetate product (pKₐ about 10). Under the conditions of the reaction, a small amount of the enolate of ethyl acetate is produced—just enough to let the reaction happen—but the product is completely converted into its enolate. The neutral product, ethyl acetoacetate itself, is formed on acidic work-up.

The final product has been formed by the acylation at carbon of the enolate of an ester. This general process—acylation at carbon—is the subject of the second part of this chapter. It so happened in this case that the acylating agent was another molecule of the same ester, but the general process we shall consider is the acylation of enolates at carbon. We shall use a variety of enols, enolates, and specific enol equivalents and a variety of acylating agents, but the basic idea is that the enolate of one carbonyl compound will have an acyl group (here the R²CO group in orange) added to the enolate carbon atom.

**Problems with acylation at carbon**

The main problem with the acylation of enolates is that reaction tends to occur at oxygen rather than at carbon.
The product of acylation on oxygen is an enol ester. The tendency to attack through oxygen is most marked with reactive enolates and reactive acylating agents. The combination of a lithium enolate and an acid chloride, for example, is pretty certain to give an enol ester.

If we want acylation at carbon we must use either:

- less reactive specific enol equivalents, such as enamines or silyl enol ethers, with reactive acylating agents such as acid chlorides or
- reactive enols, such as the enolate anions themselves, with less reactive acylating agents such as esters.

We introduced this chapter with an example of the second type of reaction, and we shall continue with a more detailed consideration of the Claisen ester condensation and related reactions.

**Reaction at oxygen—not a problem in the aldol reaction**

Earlier in this chapter, we mentioned no trouble with reaction at oxygen in the aldol reaction. This may now seem surprising, in view of what we have said about esters, as the electrophiles were aldehydes and ketones—not so very different from esters. We can resolve this by looking at what would happen if an aldehyde did attack an enolate on the oxygen atom.

The only plausible leaving group from the intermediate is the enolate oxygen: the reaction just reverses.

**The Claisen ester condensation and other self-condensations**

The self-condensation of ethyl acetate is the most famous example of the Claisen ester condensation and it works in good yield under convenient conditions. The product (ethyl acetoacetate) is commercially available for this very reason—and cheap too—so you are unlikely to want to do this particular example.

A more generally useful reaction is the self-condensation of simple substituted acetates $RCH_2CO_2Et$. These work well under the same conditions ($EtO^-$ in EtOH). The enolate anion is formed first in low concentration and in equilibrium with the ester. It then carries out a nucleophilic attack on the more abundant unenolized ester molecules.

These steps are all unfavourable equilibria and, on their own, would give very little product. However, as we mentioned before, the reaction works because the equilibrium is driven over by the essentially irreversible formation of a stable, delocalized enolate from the product.
Finally, the reaction is worked up in acid and the β keto-ester product is formed. Notice that all products of Claisen ester condensations have a 1,3-dicarbonyl relationship. These compounds are useful in the preparation of specific enol equivalents and you have seen them in action in Chapters 20 and 25, and in this chapter.

**How do we know that deprotonation drives the reaction?**

If the original ester has two substituents on the α carbon atom (C2 of the ester), the formation of the stable enolate of the product is no longer possible as there are no hydrogen atoms left to remove.

As you might expect, all the equilibria are now unfavourable, and this reaction does not go well under the normal equilibrating conditions (EtO− in EtOH). It can be made to go in reasonable yield if a stronger base is used. Traditionally, triphenylmethyl sodium is chosen. This is made from Ph3CCl and sodium metal, and is a very conjugated carbanion. Triphenylmethyl carbanion is a strong enough base to convert an ester entirely into its enolate. Reaction of the enolate with a second molecule of ester then gives the keto-ester in good yield.

**Crossed ester condensations**

Much the same arguments apply here as applied in the crossed aldol reaction. We must be quite sure that we know which compound is going to act as the enol partner and which as the acylation partner.

**Reactive esters that cannot enolize**

There are several useful esters of this kind, of which the four in the margin are the most important. They cannot act as the enol partner, and the first three are more electrophilic than most esters, so they should acylate an ester enolate faster than the ester being enolized can.

These four are arranged in order of reactivity towards nucleophiles, the most electrophilic at the top and the least electrophilic at the bottom. Oxalates are very reactive because each carbonyl group makes the other more electrophilic. The molecular LUMO is the sum of the two π* orbitals and is lower in energy than either.
Formate esters look a bit like aldehydes but their ester character dominates. The hydrogen atom just makes them very electrophilic as they lack the $\sigma$ conjugation (and steric hindrance) of simple esters.

Carbonates are particularly useful as they introduce a $\text{CO}_2\text{R}$ group on to an enolate. It is perhaps not immediately obvious why they are more electrophilic than simple esters. Normal esters are (slightly) less electrophilic than ketones because the deactivating lone pair donation by the oxygen atom is more important than the inductive effect of the electronegative oxygen atom.

The result is a small difference between two large effects. In carbonate esters there are two oxygen atoms on the same carbonyl group. Both can exert their full inductive effect but the lone pairs have to share the same $\pi^*$ orbital. The balance is changed—the summed inductive effects win out—and carbonates are more electrophilic than ordinary esters.

Finally, esters of aromatic acids cannot enolize but are less reactive than ordinary esters because of conjugation from the aromatic ring. These compounds may still be useful, as we shall see.

**Crossed Claisen ester condensations between two different esters**

To illustrate some Claisen reactions which are easy to do, we shall now give a few examples of crossed Claisen ester condensations between ordinary esters and the compounds we have just discussed. First, a reaction between a simple linear ester and diethyl oxalate performed under equilibrating conditions with ethoxide as the base. The weak base means a lower enolate concentration.

Only the simple ester can give an enolate, and the low concentration of this enolate reacts preferentially with the more electrophilic diethyl oxalate in a typical acylation
at carbon. No self-condensation of the simple ester occurs as the oxalate is much more electrophilic.

The product has an acidic hydrogen atom so it is immediately converted into a stable enolate, which is protonated on work-up in aqueous acid to give the tricarbonyl compound back again.

Another important example leads to the preparation of diethyl phenylmalonate. This compound cannot be made by ‘alkylation’ of diethyl malonate as aryl halides do not undergo nucleophilic substitution (Chapter 22).

A crossed Claisen ester condensation between very enolizable ethyl phenylacetate and unenolizable but electrophilic diethyl carbonate works very well indeed under equilibrating conditions.

Claisen condensations between ketones and esters

Claisen condensations are acylations that always involve esters as the electrophilic partner, but enolates of other carbonyl compounds—ketones, for example—may work equally well as the enol partner. In a reaction with a carbonate, only the ketone can enolize and the reactive carbonate ester is more electrophilic than another molecule of the ketone. A good example is this reaction of cyclooctanone. It does not matter which side of the carbonyl group enolizes—they are both the same.

Unsymmetrical ketones often give a single product, even without the use of a specific enol equivalent, as reaction usually occurs on the less substituted side. This is another consequence of the final enolization being the irreversible step. In this example, both possible products may form, but only one of them can form a stable enolate. Under the equilibrating conditions of the reaction, only the enolate is stable, and all the material ends up as the isomer shown.
Unsymmetrical ketones work well even when one side is a methyl group and the other a primary alkyl chain. This example gives an impressive yield and shows that, as expected, a remote alkene does not affect the reaction.

![Chemical structure](image1)

Even when both enolates can form, the less substituted dicarbonyl enolate is preferred because it constrains fewer groups to lie in the hindered plane of the tetrasubstituted enolate double bond.

![Chemical structure](image2)

Diethyl oxalate also gives well-controlled condensations with ketones and we shall take the synthesis of a new drug as an example. One way to try to prevent heart disease is to reduce the amount of ‘bad’ lipoproteins in the blood. The drug Acifran does this, and a key step in its synthesis is the base-catalysed reaction between diethyl oxalate and a methyl ketone.

![Chemical structure](image3)

Notice that the hydroxyl group on the ketone does not interfere with the reaction. No doubt the first molecule of base removes the OH proton and the second molecule forms the enolate (the only possible enolate in either molecule). Fast condensation with highly electrophilic diethyl oxalate follows. The drug itself results from simple acid treatment of this product.

![Chemical structure](image4)

The other two unenolizable esters we mentioned on p. 643 undergo cross-condensations with ketones. Unlike formaldehyde, formate esters are well behaved—no special method is necessary to correspond with the Mannich reaction in aldol chemistry. Here is what happens with cyclohexanone.

![Chemical structure](image5)

The product aldehyde is not at risk from nucleophilic attack, as it appears to be, because it immediately enolizes in base. On work-up, the product is formed as a stable enol with an intramolecular hydrogen bond.
Summary of the preparation of keto-esters by the Claisen reaction

It is worth pausing at this moment to summarize which keto-esters can be made easily by the two methods we have discussed, namely

- Claisen ester condensation
- acylation of ketones with carbonates.

Ethyl acetoacetate (ethyl 3-oxobutyrate) can of course be made by the self-condensation of ethyl acetate. This ester is cheap to buy but homologues, available by the self-condensation of other esters, are usually made in the laboratory. Which esterifying group is used (OEt, OMe, etc.) is not important as long as the same alkoxide is used as the base.

Compounds with only one of the R substituents in this structure are also easy to make. If the R substituent is at C2, it is best introduced by alkylation of the unsubstituted ester (see Chapter 25, p. 595).

Attempts to make this compound by the Claisen ester condensation would require one of the approaches in the diagram below. The dashed curly arrows suggest the general direction of the condensation required and the coloured bonds are those that would be formed if the reaction worked.

But neither reaction will work! The black route requires a controlled condensation between two different enolizable esters—a recipe for a mixture of products. The simple alkylation route above removes the need for control. The green route requires a condensation between an unsymmetrical ketone and diethyl carbonate. This condensation will work all right, but not to give this product. As you saw on p. 645, Claisen condensations prefer to give the less substituted dicarbonyl compound, and condensation would occur at the methyl group of the ketone on the right to give the other unsymmetrical keto-ester. So this isomer can be made easily too.

Making β keto-esters: a checklist

A combination of self-condensation, condensation with diethyl carbonate, and alkylation of keto-esters prepared by one of these means will allow us to make most β keto-esters that we are likely to want. Look out for all the usual problems of enolate chemistry and if any of these is a problem, try an alkylation route.

- Will the right carbonyl compound enolize?
- If it is a ketone, will it enolize in the right way?
- Will the enolate react with the right acylation partner?
Controlling acylation with specific enol equivalents

In the first part of this chapter we saw how specific enol equivalents could be used to control aldol reactions. We now need to look at the same type of control in the acylation of enolates and extend our discussion to specific enolates of carboxylic acid derivatives.

We established in Chapter 10 a hierarchy for the electrophilic reactivity of acid derivatives that should by now be very familiar to you—acyl chlorides at the top to amides at the bottom. But what about the reactivity of these same derivatives towards enolization at the position, that is, the CH₂ group between R and the carbonyl group in the various structures? You might by now be able to work this out. The principle is based on the mechanisms for the two processes.

See how similar these two mechanisms are. In particular, they are the same at the carbonyl group itself. Electrons move into the C=O π* orbital: the C=O bond becomes a C–O single bond as a negative charge develops on the oxygen atom. It should come as no surprise that the order of reactivity for enolization is the same as the order of reactivity towards nucleophilic attack. Aldehydes are more electrophilic and more easily enolized than ketones and ketones are more electrophilic and more easily enolized than esters, although exact comparisons between aldehydes and ketones on the one hand and acid derivatives on the other are unwise.

In Chapter 20 we established that enolates can be formed from acid chlorides, but that they decompose to ketenes. Enolates can be formed from amides with difficulty, but with primary or secondary amides one of the NH protons is likely to be removed instead. For the remainder of this section we shall look at how to make specific enol equivalents of acids, esters, aldehydes, and ketones.

Directed C-acylation of esters

The danger we have to face is that acylation is inclined to occur on oxygen rather than on carbon. In the extreme case, naked enolates (those with completely non-coordinating cations) acylate cleanly on oxygen with anhydrides or acid chlorides.

Fortunately, the reagents we have just discussed for aldol reactions (lithium and zinc enolates) are also acylated at carbon rather than on oxygen. Even with acid chlorides magnesium enolates, particularly those of 1,3-dicarbonyl compounds, give reliable C-acylation. The magnesium atom bonds strongly to both oxygens, lessening their effective negative charge.
Hydrolysis and decarboxylation in the usual way lead to keto-esters or keto-acids. Of the more common metals used to form enolates, lithium is the most likely to give good C-acylation as, like magnesium, it forms a strong O–metal bond. It is possible to acylate simple lithium enolates with enolizable acid chlorides.

We shall describe two examples of this reaction being used as part of the synthesis of natural products. The first is pallescensin A, a metabolite of a sponge. It is quite a simple compound and some chemists in Milan conceived that it might be made from the chloro-diketone shown below, which might in turn be made by acylation of the enolate of a symmetrical ketone.

![Chemical structure of pallescensin A and symmetrical ketone](image)

The route chosen was to react the lithium enolate of 4-t-butyl cyclohexanone with the correct acid chloride. This reaction worked well, as did the rest of the synthesis of pallescensin A, which was first made by this route. The key step, the acylation of the lithium enolate, is interesting because alkylation could have occurred instead. The acid chloride is more electrophilic than the alkyl chloride in this reaction, although alkylation does occur in the next step. Notice how the lithium atom holds the molecules together during the reaction.

![Chemical reaction of acylation](image)

Even the dilithio derivatives of carboxylic acids, made by treating a carboxylic acid with two molecules of LDA, can give good reactions with acid chlorides. In these reactions it is not necessary to have a proton remaining between the two carbonyl groups of the product as the reaction is between a strong nucleophile and a strong electrophile and is under kinetic control.

![Chemical reaction of dilithio derivatives](image)

It is rather more common to use enamines or silyl enol ethers in acylations with acid chlorides. These are more general methods—enamines work well for aldehydes and ketones while silyl enol ethers work for all classes of carbonyl compounds. It is possible to combine two enolizable molecules quite specifically by these methods, and we shall consider them next.

**The acylation of ketones via enamines and aza-enolates**

Enamines are made from secondary amines and aldehydes or ketones via the iminium salt: you met them in Chapter 11 and have seen them in action in Chapters 20 and 25. In Chapter 25 we saw that reliable C-alkylation of enamines occurs with reactive allyl halides and
α-halocarbonyl compounds, but that unwanted N-alkylation often competes with simple alkyl halides. We also noted earlier in this chapter that they are rarely used for aldol reactions as they are not reactive enough.

\[
\begin{align*}
\text{NR}_2 \quad \text{RX} \\
\end{align*}
\]

Acylation with the much more reactive acid chlorides could follow the same two pathways, but with one big difference. The products of N-acylation are unstable salts and N-acylation is reversible. Acylation on carbon, on the other hand, is irreversible. For this reason enamines end up acylated reliably on carbon.

The Swiss chemist Oppolzer used just such a reaction in a synthesis of the natural product longifolene. He first prepared an acid chloride from cyclopentadiene, and the enamine from cyclopentanone and the secondary amine morpholine.

\[
\begin{align*}
\text{Cl} \quad \text{O} \\
\end{align*}
\]

Combining the enamine with the acid chloride led to a clean acylation at carbon in 82% yield and eventually to a successful synthesis of longifolene.

Aza-enolates also react cleanly at carbon with acid chlorides. Good examples come from dimethylhydrazones of ketones. When the ketone is unsymmetrical, the aza-enolate forms on the less substituted side, even when the distinction is between primary and secondary carbons. The best of our previous regioselective acylations have distinguished only methyl from more highly substituted carbon atoms.
You will not be surprised to find that the immediate product tautomerizes to an acyl-enamine further stabilized by an internal hydrogen bond. Mild acidic work-up releases the diketone product. The overall procedure may sound complicated—Me₂NNH₂ then base then acyl chloride then acidic methanol—but it is performed in a single flask and the products, the 1,3-diketones, are formed in excellent yield—in this case 83% overall.

**Acylation of ketones under acidic conditions**

Acylations of ketone enols with anhydrides are catalysed by Lewis acids such as BF₃. This process will remind you of Friedel–Crafts acylation (p. 477) but a better analogy is perhaps the aldol reaction, where metals such as lithium hold the reagents together so that reaction can occur around a six-membered ring.

![Interactive mechanism for hydrazone enolate alkylation](image)

The mechanism obviously involves attack by the enol (or ‘boron enolate’) of the ketone on the anhydride, catalysed by the Lewis acid. Probably the boron atom holds the reagents together, much as the lithium atom does in aldol reactions of lithium enolates (p. 625).

Under the conditions of the reaction, the product forms a stable boron enolate, which needs to be decomposed to the diketone with refluxing aqueous sodium acetate.

**Acylation of free carboxylic acids**

You might think that the presence of the acidic proton in a carboxylic acid would present an insuperable barrier to the formation and use of any enol derivatives. In fact, this is not a problem with either the lithium enolates or the silyl enol ethers. Addition of BuLi or LDA to a carboxylic acid immediately results in the removal of the acidic proton and the formation of the lithium salt of the carboxylic acid. If BuLi is used, the next step is addition of BuLi to the carbonyl group and the eventual formation of a ketone (see Chapter 10, p. 218). But, if LDA is used, it is possible to form the lithium enolate of the lithium derivative of the carboxylic acid.
The enolate derivative is rather strange as it has two OLi groups on the same double bond, but it can be cleanly converted to the corresponding silyl enol ether. Both lithium enolates and silyl enol ethers from acids can be used in aldol reactions.

This concludes our general survey of specific enolates in acylation at carbon. We are left with some reactions that are particularly easy to do.

**Intramolecular crossed Claisen ester condensations**

In the same way as with intramolecular aldol condensations, we do not have to worry so much about controlling where enolization occurs providing that one product is more stable than the others—for example, it might have a five- or a six-membered ring (rather than a four- or eight-membered one)—and we carry out the reaction under equilibrating conditions. A couple of examples should show what we mean. Although there are two sites for enolate anion formation, one would give a four-membered ring and can be ignored. Only enolization of the methyl group leads to a stable six-membered ring.

In this next example the two possible sites for enolate anion formation would both lead to stable five-membered rings. The product forms a stable enolate under the reaction conditions but the alternative cannot form a stable enolate as there is no hydrogen atom between the two carbonyl groups.
In the next example, there are three possible sites for enolate anion formation, but only one product is formed and in good yield too. If we consider all three possible enolate anions, the choice is more easily made. First, the reaction that does happen. An enolate anion is formed from the ketone at the green site and acylation at carbon follows. The product is a fused rather than a bridged bicyclic structure and can easily form a stable enolate anion.

We could form the enolate anion on the other side of the ketone at the orange site and attack the ester in the same way. The product would be a bridged bicyclic diketone, and is not formed (see above). The third possible enolate site (brown) could give an aldol reaction but the product would again be a bridged bicyclic compound and is not formed.

**Symmetry in intramolecular crossed Claisen condensations**

If cyclization is to be followed by decarboxylation, a cunning plan can be set in motion. Addition of an amine by an $S_N$2 reaction to an $\alpha$-halo-ester followed by conjugate addition to an unsaturated ester gives a substrate for Claisen ester cyclization.

This diester is unsymmetrical so cyclization is likely to lead to two different keto-esters. Either can form a stable enolate so both are indeed formed. This sounds like very bad news since it gives a mixture of products.

The cunning plan is that the relative positions of the ketone and the nitrogen atom in the five-membered ring are the same in both products. All that differs is the position of the

### Bicyclic compounds

In Chapter 32 we will discuss the differences between fused compounds (one bond in common), spiro compounds (one atom in common), and bridged compounds (rings joined at two non-adjacent atoms). Each of these three examples has two five-membered rings.
CO$_2$Et group. When the two different products are hydrolysed and decarboxylated they give the same amino-ketone!

Just occasionally it is possible to carry out cross-condensations between two different enolizable molecules under equilibrating conditions. A notable example is the base-catalysed reaction between methyl ketones and lactones. With sodium hydride—a strong base that can convert either starting material entirely into its enolate anion—good yields of products from the attack of the enolate of the ketone on the electrophilic lactone can be obtained.

Kinetic enolate formation must occur at the methyl group of the ketone followed by acylation with the lactone. Lactones are rather more electrophilic than non-cyclic esters, but the control in this sequence is still remarkable. Notice how a stable enolate is formed by proton transfer within the first-formed product.

**Carbonyl chemistry—where next?**

This chapter concludes a survey of the reactions of carbonyl compounds which started way back in Chapter 6 with an introduction to addition reactions at the C=O group, and moved on through the following stages:

- Chapter 9: C–C bonds by adding organometallics to C=O
- Chapter 10: Substitution at C=O (carboxylic acid derivatives)
- Chapter 11: Substitution at C=O with loss of the carbonyl O (acetals, imines, etc.)
- Chapter 20: Enols and enolates
- Chapter 25: Alkylating enolates
- Chapter 26: Adding enols and enolates to C=O groups: the aldol and Claisen reactions

Carbonyl groups are the ‘hooks’ that allow chemists to put molecules together, and in the chapter after next (Chapter 28) we will discuss how we think about the science of synthesis using carbonyl reactivity. We will revisit many of the reactions you have seen not just in this next chapter, but beyond—in particular in the synthesis of heterocycles (Chapter 30) and in diastereoselective and enantioselective reactions (Chapters 33 and 41).

Sulfur, silicon, and phosphorus in organic chemistry

Useful main group elements

Organic chemists make use of most elements in the periodic table: you have already seen organic compounds of Li, B, F, Na, Mg, Al, Si, P, S, Cl, K, Cu, Br, and I—but that’s only the start. Three of the most important of these are sulfur, phosphorus, and silicon. They all form stable organic compounds and play nearly as important roles in organic chemistry as oxygen, nitrogen, and the halogens. They are second row elements, coming immediately below carbon, nitrogen, and oxygen, to which they have some similarity. Electronegativity (shown in the margin) diminishes from right to left and downwards.

The main difference from C, N, and O is that Si, P, and S can form more bonds than the first row elements. This is because they have more orbitals: the five 3d orbitals added to the 3s and three 3p orbitals. Silicon forms tetrahedral silanes, rather like alkanes, but also forms stable five-valent anions. Phosphorus forms phosphines, rather like amines, but also tetrahedral phosphine oxides. Sulfur can have any coordination number from zero to seven, forming sulfides, like ethers, and tetrahedral sulfones with six bonds to sulfur. And it is with sulfur that we start.

Sulfur: an element of contradictions

The first organosulfur compounds in this book were the dreadful smell of the skunk and the wonderful smell of the truffle, which pigs can detect through a metre of soil and which is so
delightful that truffles cost more than their weight in gold. Sulfur compounds can be reducing or oxidizing agents, anions or cations, nucleophiles or electrophiles as well as foul- or sweet-smelling.

Useful sulfur compounds include the leprosy drug dapsone (Chapter 6), the arthritis drug feldene (Chapter 20), glutathione (Chapter 22), a scavenger of oxidizing agents that protects most living things against oxidation and contains the natural amino acid cysteine, and, of course, the famous antibiotics, the penicillins, mentioned in several chapters.

![Sulfone](image1)

---

Important reactions include sulfur as nucleophile and leaving group in the $S_N2$ reaction, sulfonation of aromatic rings (Chapter 21), and formation and reduction of thioacetals (Chapter 23). This $S_N2$ reaction uses a sulfur nucleophile and a sulfur-based leaving group.

---

**Some facts about sulfur**

Sulfur is a p-block element in group VI (or 16 if you prefer) immediately below oxygen and between phosphorus and chlorine. It is natural for us to compare sulfur with oxygen but we will, strangely, compare it with carbon as well.

Sulfur is much less electronegative than oxygen; in fact, it has the same electronegativity as carbon, so it is no good trying to use the polarization of the $C-S$ bond to explain anything! It forms reasonably strong bonds to carbon—strong enough for the compounds to be stable but weak enough for selective cleavage in the presence of the much stronger $C-O$ bonds. It also forms fairly strong bonds to itself. Elemental crystalline yellow sulfur consists of $S_8$ molecules—eight-membered rings of sulfur atoms.

Because sulfur is in the second row of the periodic table it forms many types of compounds not available to oxygen. Compounds with $S-S$ and $S-halogen$ bonds are quite stable and can be isolated, unlike the unstable and often explosive $O-halogen$ and $O-O$ compounds. Sulfur’s $d$ orbitals allow it to have oxidation states of 0, 2, 4, or 6 and coordination numbers from 0 to 7. Here is a selection of compounds.

**Sulfur is a very versatile element**

As well as this variety of oxidation states, sulfur shows a sometimes surprising versatility in function. Simple $S(II)$ compounds are good nucleophiles, as you would expect from the
high-energy non-bonding lone pairs (3sp$^3$ rather than the 2sp$^3$ of oxygen). A mixture of a thiol (RSH, the sulfur equivalent of an alcohol) and NaOH reacts with an alkyl halide to give the sulfide alone by nucleophilic attack of RS$^-$.

Thiols (RSH) are more acidic than alcohols so the first step is a rapid proton exchange between the thiol and hydroxide ion. The thiolate anion then carries out a very efficient $S_N2$ displacement on the alkyl bromide to give the sulfide. Notice that the thiolate anion does not attack the carbonyl group. Small basic oxyanions have high charge density and low-energy filled orbitals—they are hard nucleophiles that prefer to attack protons and carbonyl groups. Large, less basic thiolate anions have high-energy filled orbitals and are soft nucleophiles. They prefer to attack saturated carbon atoms. Thiols and thiolates are good soft nucleophiles.

- Thiols (RSH) are more acidic than alcohols (ROH) but sulfur compounds are better nucleophiles than oxygen compounds towards saturated carbon atoms ($S_N2$).

They are also good soft electrophiles. Sulfenyl chlorides (RSCl) are easily made from disulfides (RS–SR) and sulfuryl chloride (SO$_2$Cl$_2$). This S(VI) chloride has electrophilic chlorine atoms and is attacked by the nucleophilic disulfide to give two molecules of RSCl and gaseous SO$_2$. There’s a lot of sulfur chemistry here! We start with a nucleophilic attack by one sulfur atom of the disulfide. The intermediate contains a tricoordinate sulfur cation or sulfonium salt. The chloride ion now attacks the other sulfur atom of this intermediate and two molecules of RSCl result. Each atom of the original disulfide has formed an S–Cl bond. One sulfur atom was a nucleophile towards chlorine and the other an electrophile.

The product of this reaction, the sulfenyl chloride, is also a good soft electrophile towards carbon atoms, particularly towards alkenes. The reaction is very like bromination, with a three-membered cyclic sulfonium ion intermediate replacing the bromonium ion of Chapter 19. The reaction is stereospecific and the product is $anti$.

At higher oxidation states the compounds become harder electrophiles as the positive charge on sulfur increases. We have already mentioned tosyl (para-toluenesulfonyl) chloride, TsCl, as an electrophile for alkoxide ions in this chapter and in earlier chapters.

At this higher oxidation state it might seem unlikely that sulfur could also be a good nucleophile, but consider the result of reacting TsCl with zinc metal. Zinc provides two electrons and turns the compound into an anion. This anion can also be drawn in two ways.
Surprisingly, this anion is also a good soft nucleophile and attacks saturated carbon atoms through the sulfur atom. In this case attack occurs at the less substituted end of an allylic bromide to give an allylic sulfone, which we will use later on.

- Sulfur compounds may be good nucleophiles and good electrophiles.

### Sulfur-based functional groups

You have already met a number of sulfur-containing functional groups: the following list brings them together for reference.

As this chapter develops you will see other examples of the versatility of sulfur. You will see that it can be removed from organic compounds in either an oxidative or a reductive fashion, and you will see that it can stabilize anions or cations on adjacent carbon atoms. The stabilization of anions is the first main section of the chapter.

**Sulfur-stabilized anions**

The stabilization of anions by sulfides, sulfoxides, and sulfones is a theme that runs right through this chapter. Sulfur has six electrons in its outer shell. As a sulfide, therefore, the sulfur atom carries two lone pairs. In a sulfoxide, one of these lone pairs is used in a bond to an oxygen atom—sulfoxides can be represented in at least two alternative but equivalent ways. The sulfur atom in a sulfone uses both of its lone pairs in bonding to oxygen, and is usually represented with two $S=O$ double bonds.

![Methyl phenyl sulfide](image1)

![Methyl phenyl sulfoxide](image2)

![Methyl phenyl sulfone](image3)

**Chiral sulfoxides**

Sulfoxides have the potential for chirality—the tetrahedral sulfur atom is surrounded by four different groups (here Ph, Me, O, and the lone pair) and (unlike, say, the tetrahedral nitrogen atom of an amide) has a stable tetrahedral configuration. We will revisit chirality in sulfoxides later in the chapter.

![Enantiomers of a chiral sulfoxide](image4)

Treatment of any of these compounds with strong base produces an anion on what was the methyl group. How does the sulfur stabilize the anion? This question has been the subject of many debates and we have not got space to go into the details of all of them. There are at least two factors involved, and the first is evident from this chart of $pK_a$ values for protons next to sulfone, sulfoxide, and sulfide functional groups.

<table>

</table>

Clearly, the oxygen atoms are important—the best anion stabilizer is the sulfone, followed by the sulfoxide and then the sulfide. You could compare deprotonation of a sulfone with deprotonation of a ketone to give an enolate (Chapter 20). Enolates have a planar carbon atom and the anion is mainly on the oxygen atom. Sulfone-stabilized carbanions have two oxygen atoms and the anionic carbon atom is probably planar, with the negative charge in a $p$ orbital aligned midway between the $S=O$ bonds.

![Planar enolate](image5)

![Sulfone-stabilized anion](image6)
Yet the attached oxygen atoms cannot be the sole reason for the stability of anions next to sulfur because even the sulfide functional group also acidifies an adjacent proton quite significantly. There is some controversy over exactly why this should be, but the usual explanation is that polarization of the sulfur's 3s and 3p electrons (which are more diffuse, and therefore more polarizable, than the 2s and 2p electrons of oxygen) contributes to the stabilization.

**Anion stabilization by adjacent sulfur**

It was long thought that delocalization into sulfur's empty 3 orbitals provided the anion stabilization required, but theoretical work in the last 20 years or so suggests this may not be the case. Thus, *ab initio* calculations suggest that the C–S bond in −CH₂SH is longer than that in CH₃SH. The converse would be true if delocalization into the sulfur's d orbitals were important. Delocalization would shorten the bond because it would have partial double-bond character. More likely as an additional factor is delocalization into the σ* orbital of the C–S bond on the other side of the sulfur atom—the equatorial proton of dithiane (see p. 662 for more on dithiane) is more acidic than the axial one, and the equatorial anion is more stable because it is delocalized into the C–S bond's σ* orbital.

**A sulfoxide-stabilized anion in a synthesis**

A sulfoxide alkylation formed the key step of a synthesis of the important vitamin biotin. Biotin contains a five-membered heterocyclic sulfide fused to a second five-membered ring, and the bicyclic skeleton was easy to make from a simple symmetrical ester. The vital step is a double SN₂ reaction on primary carbon atoms.

The next step was to introduce the alkyl chain—this was best done by first oxidizing the sulfide to a sulfoxide, using sodium periodate. The sulfoxide was then deprotonated with *n*-BuLi and alkylated with an alkyl iodide containing a carboxylic acid protected as its tert-butyl ester. Reduction of the sulfoxide and hydrolysis back to the free acid gave biotin.

**Thioacetals**

Although sulfide deprotonations are possible, the protons adjacent to two sulfide sulfur atoms are rather more acidic and alkylation of thioacetals is straightforward.
In general, thioacetals can be made in a similar way to ‘normal’ (oxygen-based) acetals—by treatment of an aldehyde or a ketone with a thiol and an acid catalyst—although a Lewis acid such as BF₃ is usually needed rather than a protic acid. The most easily made, most stable toward hydrolysis, and most reactive towards alkylation are cyclic thioacetals derived from 1,3-propanedithiol, known as dithianes.

Dithianes are extremely important compounds in organic synthesis because going from carbonyl compound to thioacetal inverts the polarity at the functionalized carbon atom. Aldehydes, as you are well aware, are electrophiles at the C=O carbon atom, but dithioacetals, through deprotonation to an anion, are nucleophilic at this same atom.

**Dithianes in synthesis**

An example: chemists wanted to make this compound (a ‘metacyclophane’) because they wanted to study the independent rotation of the two benzene rings, which is hindered in such a small ring. An ideal way would be to join electrophilic benzylc bromides to nucleophilic carbonyl groups, if that were possible.

The dibromide and dialdehyde were both available—what they really wanted was a nucleophilic equivalent of the dialdehyde to react with the dibromide. So they made the dithiane. Sulfur is less basic than oxygen, so the protonated species is lower in concentration at a given pH, and the sulfur 3p lone pairs are less able to form a stable π bond to carbon than are the oxygen 2p lone pairs.

After the dithianes have been alkylated, they can be hydrolysed to give back the carbonyl groups. Alternatively, hydrogenation using Raney nickel replaces the thioacetal with a CH₂ group and gives the unsubstituted cyclophane.
Dithianes are rather more stable than acetals, and special reagents have to be used to assist their hydrolysis and reveal the hidden carbonyl group. Sulfur is less basic than oxygen, so the protonated species is lower in concentration at a given pH, and the sulfur 3p lone pairs are less able to form a stable π bond to carbon than are the oxygen 2p lone pairs.

\[
\begin{align*}
\text{poor reaction...} & \quad \text{good reaction...} \\
\begin{array}{c}
\text{weakly basic} \\
\text{lone pairs}
\end{array} & \quad \begin{array}{c}
\text{higher concentration}
\end{array} & \quad \begin{array}{c}
\text{strong O=\(\pi\) bond}
\end{array}
\end{align*}
\]

- Sulfur compounds are less basic than oxygen compounds and C=S compounds are less stable than C=O compounds.

The most obvious solution to this problem is to provide a better electrophile than the proton for sulfur. Mercury, Hg(II), is one solution. Another is oxidation of one sulfur to the sulf oxide. Protonation can now occur on the more basic oxygen atom of the sulfoxide and the concentration of the vital intermediate is increased.

A third solution is methylation, since sulfur is a better nucleophile than oxygen for saturated carbon. The sulfonium salt can decompose in the same way to give the free aldehyde. There are many more methods for hydrolysing dithioacetals and their multiplicity should make you suspicious that none is very good.

Hydrogenation of C–S bonds in both sulfi des and thioacetals is often achieved with Raney nickel, the finely divided form of nickel made by dissolving away the aluminium from a powdered nickel–aluminium alloy using alkali. It can be used either as a catalyst for hydrogenation with gaseous hydrogen or as a reagent since it often contains sufficient adsorbed hydrogen (from the reaction of aluminium with alkali) to effect reductions alone. Thioacetalization followed by Raney nickel reduction is a useful way of replacing a C=O group with CH₂.

**Dithianes are ‘acyl anion equivalents’**

A sequence in which a carbonyl group has been masked as a sulfur derivative, alkylated with an electrophile, and then revealed again is a nucleophilic acylation. These nucleophilic equivalents of carbonyl compounds are known as acyl anion equivalents. In the retrosynthetic terms of Chapter 28 they are d¹ reagents corresponding to the acyl anion synthon.

**Anions from sulfones**

If the sulfur is at a higher oxidation level, it is much easier to make adjacent anions, and sulfones excel in this regard. The allylic sulfone we made earlier in the chapter (p. 659) can be deprotonated and added to an unsaturated ester to give a cyclopropane. Notice how much weaker a base (MeO⁻) is needed here, as the anion is stabilized by sulfone and alkene.
The first step is conjugate addition of the highly stabilized anion. The intermediate enolate then closes the three-membered ring by favourable nucleophilic attack on the allylic carbon. The leaving group is the sulfinate anion and the stereochemistry comes from the most favourable arrangement in the transition state for this ring closure. The product is the methyl ester of the important chrysanthemic acid found in the natural pyrethrum insecticides.

**Sulfonium salts**

Sulfides are nucleophiles even when not deprotonated—the sulfur atom will attack alkyl halides to form sulfonium salts. This is, of course, a familiar pattern of reactivity for amines, and you have seen phosphonium salts formed in a similar way.

This reaction is an equilibrium and it may be necessary in making sulfonium salts from less reactive sulfides (sterically hindered ones, for example) to use more powerful alkylating agents with non-nucleophilic counterions, for example Me₃O⁺BF₄⁻, trimethyloxonium fluoroborate (also known as Meerwein’s salt). The sulfur atom captures a methyl group from O⁺, but the reverse does not happen and the BF₄⁻ anion is not a nucleophile. Not only is dimethyl ether a poor nucleophile, it is also a gas and is lost from the reaction mixture. The same principle is used to make sulfides from other sulfides.

The most important chemistry of sulfonium salts is based on one or both of two attributes:

1. Sulfonium salts are electrophiles: nucleophilic substitution displaces a neutral sulfide leaving group.
2. Sulfonium salts can be deprotonated to give sulfonium ylids.

**Sulfonium salts as electrophiles**

During the First World War, mustard gas was developed as a chemical weapon—it causes the skin to blister and is an intense irritant of the respiratory tract. Its reactivity towards human tissue is related to the following observation and is gruesome testimony to the powerful electrophilic properties of sulfonium ions.

This reaction goes 600 times faster than...
In both cases, intramolecular displacement of the chloride leaving group by the sulfur atom—or, as we should call it, participation by sulfur—gives a three-membered cyclic sulfonylum ion intermediate (an episulfonium or thiiranium ion). Nucleophilic attack on this electrophilic sulfonylum ion, either by water or by the structural proteins of the skin, is very fast. Of course, mustard gas can react twice in this way. You will see several more examples of reactions in which a sulfonylum ion intermediate acts as an electrophile in the next section.

**Sulfonylum ylids**

The positive charge carried by the sulfur atom means that the protons next to the sulfur atom in a sulfonylum salt are significantly more acidic than those in a sulfide, and sulfonylum salts can be deprotonated to give sulfonylum ylids.

In Chapter 11 we discussed the Wittig reaction of phosphonium ylids with carbonyl compounds. Sulfonylum ylids react with carbonyl compounds too, but in quite a different way—compare these two reactions.

Phosphonium ylids give alkenes while sulfonylum ylids give epoxides. Why should this be the case? The driving force in the Wittig reaction is formation of the strong P=O bond—that force is much less in the sulfur analogues (the P=O bond strength in Ph₃PO is 529 kJ mol⁻¹; in Ph₂SO the S=O bond strength is 367 kJ mol⁻¹). The first step is the same in both reactions: the carbanion of the ylid attacks the carbonyl group in a nucleophilic addition reaction. The intermediate in the Wittig reaction cyclizes to give a four-membered ring but this does not happen with the sulfur ylids. Instead, the intermediate decomposes by intramolecular nucleophilic substitution of Me₂S by the oxyanion.

Sulfonylum ylids are therefore useful for making epoxides from aldehydes or ketones; other ways you have met of making epoxides (Chapter 19) started with alkenes that might themselves be made with phosphorus ylids.

Some chemists working on a route to some potential β-blocker drugs needed the epoxide below, and since 4-cyclopropylbenzaldehyde was more readily available than 4-cyclopropyl styrene, they decided to use the aldehyde as the starting material and make the epoxide in one step using a sulfonylum ylid.
'Stabilized' sulfonium ylids

If there is a conjugating group on the carbanion carbon atom of the ylid, the ylid is more stable and its reactions may change. Firstly, an example where the ylid is stabilized by a cyanide. As you have just seen, the simple sulfonium ylid gives the epoxide from this α,β-unsaturated ketone. But the ‘stabilized’ ylid gives the cyclopropane instead.

In the absence of the conjugated alkene, both types of ylid give epoxides—the ester-stabilized ylid, for example, reacts with the diketone known as benzil to give an epoxide but with methyl vinyl ketone (but-3-en-2-one) to give a cyclopropane.

Why does the stabilized ylid prefer to react with the double bond? The enone has two electrophilic sites, but from Chapter 22, in which we discussed the regioselectivity of attack of nucleophiles on Michael acceptors like this, you would expect that direct 1,2-attack on the ketone is the faster reaction. This step is irreversible, and subsequent displacement of the sulfide leaving group by the alkoxide produces an epoxide. Whether a cyclopropane product would have been more stable is irrelevant to the outcome: the epoxide forms faster and is therefore the kinetic product.

With a stabilized ylid, direct addition to the carbonyl group is, in fact, probably still the faster reaction. But in this case, the starting materials are sufficiently stable that the reaction is reversible, and the sulfonium ylid is re-expelled before the epoxide has a chance to form. Meanwhile, some ylid adds to the ketone in a 1,4 (Michael or conjugate) fashion. 1,4-Addition, although slower, is energetically more favourable because the new C–C π bond is gained at the expense of a (relatively) weak C=C π bond rather than a (relatively) strong C=O π bond, and is therefore irreversible. Eventually, all the ylid ends up adding in a 1,4-fashion, generating an enolate as it does so, which cyclizes to give the cyclopropane, which is the thermodynamic product. This is another classic example of kinetic versus thermodynamic control, and you can add it to your mental list of examples.
Sulfoxonium ylids

There is another, very important, class of stabilized sulfur ylids that owe their stability not to an additional anion-stabilizing substituent but to a more anion-stabilizing sulfur group. These are the sulfoxonium ylids, made from dimethylsulfoxide by SN2 substitution with an alkyl halide. Note that the sulfur atom is the nucleophile rather than the oxygen atom in spite of the charge distribution. The high-energy sulfur lone pair is better at SN2 substitution at saturated carbon—a reaction that depends very little on charge attraction (Chapter 15).

Sulfoxonium ylids react with unsaturated carbonyl compounds in the same way as the stabilized ylids that you have met already—they form cyclopropanes rather than epoxides. The example below shows one consequence of this reactivity pattern—by changing from a sulfonium to a sulfoxonium ylid, high yields of either epoxide or cyclopropane can be formed from an unsaturated carbonyl compound (this one is the terpene known as carvone).

The Swern oxidation

This important reaction featured briefly in Chapter 23 as an important method of oxidizing alcohols to aldehydes. We said there that we would discuss this interesting reaction later and now is the time.

In the first step, DMSO reacts with oxaly chloride to give an electrophilic sulfur compound. You should not be surprised that it is the charged oxygen atom that attacks the carbonyl group rather than the soft sulfur atom. Chloride is released in this acylation and it attacks the positively charged sulfur atom, expelling a remarkable leaving group that fragments into three pieces: CO2, CO, and a chloride ion. Entropy favours this reaction.
The alcohol has been a spectator in these events so far but the chlorosulfonium ion now formed can react with it to give a new sulfonium salt. This is the sole purpose of all the reactions up to this point. This sulfonium salt is deprotonated by the base (Et$_3$N) to form an ylid. The final step completes the redox reaction: the transfer of a proton to the anionic carbon gives an aldehyde, with overall reduction of dimethylsulfoxide (DMSO) to dimethylsulfide (DMS).

### Silicon and carbon compared

Silicon is immediately below carbon in the periodic table and the most obvious similarity is that both elements normally have a valency of four and both form tetrahedral compounds. There are important differences in the chemistry of carbon and silicon—silicon is less important and many books are devoted solely to carbon chemistry but relatively few to silicon chemistry. Carbon forms many stable trigonal and linear compounds containing π bonds; silicon forms few. The most important difference is the strength of the silicon–oxygen σ bond (368 kJ mol$^{-1}$) and the relative weakness of the silicon–silicon (230 kJ mol$^{-1}$) bond. Together these values account for the absence, in the oxygen-rich atmosphere of earth, of silicon analogues of the plethora of structures possible with a carbon skeleton.

<tr>
<td>Si</td>
</tr>
</tbody>
</table>

Several of the values in the table give insight into the reactivity differences between carbon and silicon. Bonds to electronegative elements are generally stronger with silicon than with carbon; in particular, the silicon–fluorine bond is one of the strongest single bonds known, while bonds to electropositive elements are weaker. Silicon–hydrogen bonds are much weaker than their carbon counterparts and can be cleaved easily. Here are a few organosilicon compounds.

In this section we will mostly discuss compounds with four Si–C bonds. Three of these bonds will usually be the same so we will often have a Me$_3$Si group attached to an organic molecule. We shall discuss reactions in which something interesting happens to the organic molecule as one of the Si–C bonds reacts to give a new Si–F or Si–O bond. We shall also discuss organosilicon compounds as reagents, such as triethylsilane (Et$_3$SiH), which is a reducing agent whereas Et$_3$C–H is not.
The carbon–silicon bond is strong enough for the trialkyl silyl group to survive synthetic transformations on the rest of the molecule but weak enough for it to be cleaved specifically when we want. In particular, fluoride ion is a poor nucleophile for carbon compounds but attacks silicon very readily. Another important factor is the length of the C–Si bond (1.89 Å)—it is significantly longer than a typical C–C bond (1.54 Å). Silicon has a lower electronegativity (1.8) than carbon (2.5) and therefore C–Si bonds are polarized towards the carbon. This makes the silicon susceptible to attack by nucleophiles. The strength of the C–Si bond means that alkyl silanes are stable but the most useful chemistry arises from carbon substituents other than simple alkyl groups.

**Silicon has an affinity for electronegative atoms**

The most effective nucleophiles for silicon are the electronegative ones that will form strong bonds to silicon. Those based on oxygen or halide ions (chloride and fluoride) are pre-eminent. You saw this in the choice of reagent for the selective cleavage of silyl ethers in Chapter 23. Tetrabutylammonium fluoride is often used as this is an organic-soluble ionic fluoride and forms a silyl fluoride as the by-product. The mechanism is not a simple SN2 process and has no direct analogue in carbon chemistry. It looks like a substitution at a hindered tertiary centre, which ought to be virtually impossible. Two characteristics of silicon facilitate the process: the long silicon–carbon bonds relieve the steric interactions and the d orbitals of silicon provide a target for the nucleophile that does not have the same geometric constraints as a C–O σ* orbital.

Attack of the fluoride on the empty d orbital leads to a negatively charged pentacoordinate intermediate that breaks down with loss of the alkoxide. The discrete pentacoordinate trigonal bipyramid intermediate contrasts with the similarly shaped pentacoordinate transition state of a carbon-based SN2 reaction. It is often omitted in mechanistic schemes because it is formed slowly and decomposes quickly, and the mechanism is still referred to as ‘SN2 at silicon’.

**Nucleophilic substitution at silicon**

You may wonder why trimethylsilyl chloride does not use the SN1 mechanism familiar from the analogous carbon compound t-buty!l chloride. There is, in fact, nothing wrong with the Me₃Si⁺ cation—it can be detected in mass spectra, for example. The reason is simply that the ‘SN2’ reaction at silicon is too good for SN1 to compete.
When a Me₃Si group is removed from an organic molecule with hydroxide ion, the product is not the silanol as you might expect but the silyl ether ‘hexamethyldisiloxane’.

The other side of the coin is that the Sₙ2 reaction at carbon is not much affected by partial positive charge (δ⁺) on the carbon atom. The ‘Sₙ2’ reaction at silicon is affected by the charge on silicon. The most electrophilic silicon compounds are the silyl triflates and it is estimated that they react some $10^8$–$10^9$ times faster with oxygen nucleophiles than do silyl chlorides. Trimethylsilyl triflate is, in fact, an excellent Lewis acid and can be used to form acetals or silyl enol ethers from carbonyl compounds, and to react these two together in aldol-style reactions. In all three reactions the triflate attacks an oxygen atom. In the acetal formation, silylation occurs twice at the carbonyl oxygen atom and the final leaving group is hexamethyldisiloxane.

You should compare this with the normal acid-catalysed mechanism described in Chapter 11, where the carbonyl group is twice protonated and the leaving group is water.

**Silyl ethers are versatile protecting groups for alcohols**

Silicon-based protecting groups for alcohols are the best because they are the most versatile. They are removed by nucleophilic displacement with fluoride or oxygen nucleophiles and the rate of removal depends mostly on the steric bulk of the silyl group. The simplest is trimethylsilyl (Me₃Si or often just TMS), which is also the most easily removed as it is the least hindered. In fact, it is removed so easily by water with a trace of base or acid that special handling is required to keep this labile group in place. These protecting groups are discussed in Chapter 23.

Replacement of the one of the methyl groups with a much more sterically demanding tertiary butyl group gives the t-butyldimethylsilyl (TBDMS) group, which is stable to normal handling and survives aqueous work-up or column chromatography on silica gel. The stability to these isolation and purification conditions has made TBDMS (sometimes over-abbreviated to TBS) a very popular choice for organic synthesis. TBDMS is introduced by a substitution reaction on the corresponding silyl chloride with imidazole in DMF. Yields are usually virtually quantitative and the conditions are mild. Primary alcohols are protected in the presence of secondary alcohols. Removal relies on the strong affinity of fluoride for silicon and is usually very efficient and selective.

However, a protecting group is useful only if it can be introduced and removed in high yield without affecting the rest of the molecule and if it can survive a wide range of conditions in the course of the synthesis. The extreme steric bulk of the t-butyldiphenylsilyl (TBDPS) group makes it useful for selective protection of unhindered primary alcohols in the presence of secondary alcohols.

The most stable common silyl protecting group (trisopropylsilyl or TIPS) has three branched alkyl substituents to protect the central silicon from attack by nucleophiles, which would lead to cleavage. All three hindered silyl groups (TBDMS, TBDPS, and TIPS) have excellent stability but can still be removed with fluoride.
The Peterson elimination

There are many reactions in organic chemistry in which an Me₃Si group acts like a proton. Just as acidic protons are removed by bases, silicon is readily removed by hard nucleophiles, particularly F⁻ or RO⁻, and this can promote an elimination. An example is shown here.

This reaction is known as the Peterson elimination. It is rather like those we discussed in Chapter 17—eliminations of alcohols under acidic conditions to give alkenes. But, unlike those reactions, it is fully regioselective and so is particularly useful for making double bonds where other elimination methods might give the wrong regioisomer or mixtures of regioisomers. In this next example only one product is formed, in high yield, and it has an exocyclic double bond. Just think what would have happened without the silicon atom (ignore the one attached to the oxygen—that’s just a protecting group). This compound is, in fact, an intermediate in a synthetic route to the important anticancer compound Taxol.

The Peterson reaction is particularly useful for making terminal or exocyclic double bonds connectively because the starting material (the magnesium derivative shown above) is easily made from available Me₃SiCH₂Br.

Alkynyl silanes are used for protection and activation

Terminal alkynes have an acidic proton (pKₐ ca. 25) that can be removed by very strong bases such as organometallic reagents (Grignards, RLi, etc.). While this is often what is intended, in other circumstances it may be an unwanted side reaction that would consume an organometallic reagent or interfere with the chosen reaction. Exchange of the terminal proton of an alkyne for a trimethylsilyl group exploits the relative acidity of the proton and provides a neat solution to these problems. The SiMe₃ group protects the terminus of the alkyne during the reaction but can then be removed with fluoride or sodium hydroxide. A classic case is the removal of a proton next door to a terminal alkyne.

Additionally, acetylene itself is a useful two-carbon building block but is not very convenient to handle as it is an explosive gas. Trimethylsilylacetylene is a distillable liquid that is a convenient substitute for acetylene in reactions involving the lithium derivative as it has only one acidic proton. The synthesis of this alkynyl ketone is a classic case of deprotonation with butyl lithium provides the alkynyl ketone as an example. Deprotonation with butyl lithium provides the alkynyl ketone that reacted with the alkyl chloride in the presence of iodide as nucleophilic catalyst (see Chapter 15). Removal of the trimethylsilyl
group with potassium carbonate in methanol allowed further reaction on the other end of the alkyne.

**Silicon stabilizes a positive charge on the β carbon**

In common with ordinary alkynes, silylated alkynes are nucleophilic towards electrophiles. The presence of the silicon has a dramatic effect on the regioselectivity of this reaction: attack occurs only at the atom directly bonded to the silicon. This must be because the intermediate cation is stabilized.

![Diagram of silicon stabilization](image)

The familiar hierarchy of carbocation stability—tertiary > secondary > primary—is due to the stabilization of the positive charge by donation of electron density from adjacent C–H or C–C bonds (their filled σ orbitals to be precise) that are aligned correctly with the vacant orbital. The electropositive nature of silicon makes C–Si bonds even more effective donors: a silyl group β to a positive charge (i.e., attached to the next-door carbon) stabilizes a positive charge so effectively that the course of a reaction involving cationic intermediates is often completely controlled. This is stabilization by σ donation.

![Diagram of carbocation stabilization](image)

The stabilization of the cation also weakens the C–Si bond by delocalization so that the bond is more easily broken. Attack of a nucleophile (particularly a halogen or oxygen nucleophile) on silicon removes it from the organic fragment and the net result is electrophilic substitution in which the silicon has been replaced by the electrophile.

This is useful for the synthesis of alkynyl ketones, which are difficult to make directly with conventional organometallic reagents such as alkynyl–Li or –MgBr because they add a second time to the ketone product. Alkynyl silanes react in a Friedel–Crafts manner with acid chlorides in the presence of Lewis acids, such as aluminium chloride, to give the ketones.

**Aryl silanes undergo ipso substitution with electrophiles**

Exactly the same sort of mechanism accounts for the reactions of aryl silanes with electrophiles under Friedel–Crafts conditions. Instead of the usual rules governing ortho, meta, and para substitution using the directing effects of the substituents, there is just one rule: the silyl group is replaced by the electrophile at the same atom on the ring—this is known as **ipso**
substitution. Actually, this selectivity comes from the same principles as those used for ordinary aromatic substitution (Chapter 21): the electrophile reacts to produce the most stable cation—in this case \( \beta \) to silicon. Cleavage of the weakened C–Si bond by any nucleophile leads directly to the ipso product.

There is an alternative site of attack meta to silicon that would lead to a cation \( \beta \) to Si. But this cation is not particularly stable because the vacant p orbital is orthogonal to the C–Si bond and so cannot interact with it as the C–Si bond is still in the plane of the ring. This illustrates that it is more important to understand the origin of the effect based on molecular orbitals rather than simply to remember the result.

This reactivity of aryl silanes is used to convert stable phenyldimethylsilyl compounds into more reactive compounds such as alcohols by a reaction such as that shown in the margin. Several reagents can be used, all of which induce ipso substitution of the phenyl silane. The reaction with bromine is typical. Bromobenzene is produced together with a silyl bromide that is activated towards subsequent oxidation.

The mechanism of electrophilic desilylation is the same as that for electrophilic aromatic substitution except that the proton is replaced by the trimethylsilyl group. The silicon stabilizes the intermediate cation, and hence the transition state leading to it, to such an extent that the rate is many orders of magnitude faster. This is the first step with bromine.

The rest of the reaction sequence involves displacement of Br\(^-\) by HOO\(^-\), addition of hydroxide, rearrangement, and hydrolysis.

Vinyl silanes offer a regio- and stereoselective route to alkenes

Vinyl silanes react with electrophiles in a similarly regioselective process in which the silicon is replaced by the electrophile at the ipso carbon atom. The stereochemistry of the vinyl silane is important because this exchange usually occurs with retention of geometry as well.
This is a curious and interesting reaction that deserves explanation. Addition of the electrophile next to silicon leads to the more stable cation \( \beta \) to silicon. In the vinyl silane the C–Si bond is orthogonal to the p orbitals of the \( \pi \) bond, but as the electrophile attacks the \( \pi \) bond, say from underneath, the Me\(_3\)Si group starts to move upwards. As it rotates, the angle between the C–Si bond and the remaining p orbital decreases from 90°. As the angle decreases, the interaction between the C–Si bond and the empty p orbital of the cation increases. There is every reason for the rotation to continue in the same direction and no reason for it to reverse. The diagram shows that, in the resulting cation, the electrophile is in the position formerly occupied by the Me\(_3\)Si group, \( \text{trans} \) to Ph. Loss of the group now gives retention of stereochemistry.

The intermediate cation has only a single bond and so rotation might be expected to lead to a mixture of geometrical isomers of the product but this is not observed. The bonding interaction between the C–Si bond and the empty p orbital means that rotation is restricted. This stabilization weakens the C–Si bond and the silyl group is quickly removed before any further rotation can occur. The stabilization is effective only if the C–Si bond is correctly aligned with the vacant orbital, which means it must be in the same plane—rather like a \( \pi \) bond. Here is the result for both \( E \) and \( Z \) isomers of the vinyl silane.

It is unusual for silicon to be required in the final product of a synthetic sequence and the stereospecific removal of silicon from vinyl silanes makes them useful reagents that can be regarded as rather stable vinylc organometallic reagents that will react with powerful electrophiles, preserving the double bond location and geometry. Protodesilylation, as the process of replacing silicon with a proton is known, is one such important reaction. The halogens are also useful electrophiles while organic halides, particularly acid chlorides, in the presence of Lewis acids, form vinyl halides and unsaturated ketones of defined geometry.
**Allyl silanes as nucleophiles**

If the silyl group is moved along the carbon chain by just one atom, an allyl silane results. Allyl silanes can be produced from allyl organometallic reagents but there is often a problem over which regioisomer is produced and mixtures often result. Better methods control the position of the double bond. Two useful examples take advantage of the Wittig reaction and the Peterson elimination to construct the alkene linkage. The reagents are prepared from trimethylsilyl halides either by formation of the corresponding Grignard reagent or alkylation with a primary Wittig reagent and deprotonation to form a new ylid. The Grignard reagent, with added cerium trichloride, adds twice to esters to give the corresponding tertiary alcohol, which loses one of its Me₃Si groups in a Peterson elimination to reveal the remaining Me₃Si group as part of allyl silane.

![Chemical structure showing the formation of allyl silane from Grignard reagent and Peterson elimination](image)

The Wittig reagent is made by alkylation of the simplest ylid with the same silicon reagent. Notice that the leaving group (iodide) is on the carbon next to silicon, not on the silicon itself. Anion formation occurs next to phosphorus because Ph₃P⁺ is much more anion-stabilizing than Me₃Si. The ylid reacts with carbonyl compounds such as cyclohexanone in the usual way to produce the allyl silane with no ambiguity over which end of the allyl system is silylated.

![Chemical structure showing the formation of allyl silane from Wittig reaction](image)

The carbon–silicon bond has two important effects on the adjacent alkene. The presence of a high-energy filled σ orbital of the correct symmetry to interact with the π system produces an alkene that is more reactive with electrophiles, due to the higher-energy HOMO, and the same σ orbital stabilizes the carbocation if attack occurs at the remote end of the alkene. This lowers the transition state for electrophilic addition and makes allyl silanes much more reactive than isolated alkenes.

**Allyl silanes are more reactive than vinyl silanes but also react through β-silyl cations**

Vinyl silanes have C–Si bonds orthogonal to the p orbitals of the alkene—the C–Si bond is in the nodal plane of the π bond—so there can be no interaction between the C–Si bond and the π bond. Allyl silanes, by contrast, have C–Si bonds that can be, and normally are, parallel to the p orbitals of the π bond so that interaction is possible.

![Chemical structure showing the interaction between parallel orbitals compared to orthogonal orbitals](image)

Allyl silanes react with electrophiles with even greater regioselectivity than that of vinyl silanes. The cation β to the silyl group is again formed but there are two important differences. Most obviously, the electrophile attacks at the other end of the allylic system and there is no rotation necessary as the C–Si bond is already in a position to overlap efficiently with the intermediate cation. The process is terminated by loss of silicon in the usual way to regenerate an alkene.
Molecular orbitals demonstrate the smooth transition from the allyl silane, which has a π bond and a C–Si σ bond, to the allylic product with a new π bond and a new σ bond to the electrophile. The intermediate cation is mainly stabilized by σ donation from the C–Si bond into the vacant p orbital but it has other σ-donating groups (C–H, C–C, and C–E) that also help. The overall process is electrophilic substitution with allylic rearrangement. Both the site of attachment of the electrophile and the position of the new double bond are dictated by the silicon.

Allyl silanes are rather like silyl enol ethers: they react with electrophiles, provided they are activated, for example by a Lewis acid. Titanium tetrachloride is widely used but other successful Lewis acids include boron trifluoride, aluminium chloride, and trimethylsilyl triflate. Electrophiles include acylium ions produced from acid chlorides, carbocations from tertiary halides or secondary benzylic halides, activated enones, and epoxides all in the presence of Lewis acid. In each case the new bond is highlighted in black.

**β-Silyl cations are important intermediates**

Vinyl and aryl silanes react with electrophiles at the same (ipso or α) atom occupied by silicon. Allyl silanes react at the end of the alkene furthest from silicon (γ). In both cases a β-silyl cation is an intermediate.

**Lewis acids promote couplings via oxonium ions**

Allyl silanes will also attack carbonyl compounds when they are activated by coordination of the carbonyl oxygen atom to a Lewis acid. The Lewis acid, usually a metal halide such as TiCl₄ or ZnCl₂, activates the carbonyl compound by forming an oxonium ion with a metal–oxygen bond. The allyl silane attacks in the usual way and the β-silyl cation is desilylated with the halide ion. Hydrolysis of the metal alkoxide gives a homoallylic alcohol.
A closely related reactive oxonium ion can be prepared by Lewis acid catalysed breakdown of the corresponding acetal. Alternatively, especially if the acetal is at least partly a silyl acetal, the same oxonium ion can be produced \textit{in situ} using yet more silicon in the form of TMSOTf as the Lewis acid catalyst. All these intermediate oxonium ions act as powerful electrophiles towards allyl silanes, producing homoallylic alcohols or ethers.

The regiocontrol that results from using an allyl silane to direct the final elimination is illustrated by this example of an intramolecular reaction on to an acetal promoted by tin tetrachloride. The same reaction can be run in the absence of silicon but the intermediate cation can then lose a range of protons to produce five different products!

---

**The selective synthesis of alkenes**

S, Si, P, and other main group elements have several important functions in organic chemistry, and one in which all of S, Si, and P each play a star role is in the synthesis of alkenes. You have met alkenes participating in reactions in a number of chapters, but our discussion of how to make alkenes has so far been quite limited. Chapter 17 was about elimination reactions, and there you met E1 and E2 reactions. You had a glimpse of the importance of phosphorus in alkene synthesis in Chapter 11, where you met the Wittig reaction, and earlier in this chapter you saw silicon participating in the Peterson elimination. We're now going to look at related reactions in more detail, addressing especially how to form alkenes with control over their geometry. First we need to establish that this is an important task and remind you of some reactions you have already met that can be used for it.

**The properties of alkenes depend on their geometry**

Geometrical isomers of alkenes are different compounds with different physical, chemical, and biological properties. They are often hard to separate by chromatography or distillation, so it is important that chemists have methods for making them as single isomers.
Different biological properties: juvenile hormone as a pest control

If insect pests can be prevented from maturing they fail to reproduce and can thus be brought under control. Juvenile insects control their development by means of a ‘juvenile hormone’, one of which is the monoepoxide of a triene:

\[
\text{cecropia juvenile hormone: activity} = 1000
\]

Synthetic analogues of this compound, such as the trienes below, are also effective at arresting insect development, providing that the double bond geometry is controlled. The \(Z,E,E\) geometrical isomer of the triene is over twice as active as the \(E,E,E\) isomer, and over 50 times as active as the \(Z,Z,E\) or \(Z,E,Z\) isomers.

activité of juvenile hormone analogues (natural hormone = 1000)

\[
\begin{align*}
\text{the } Z,E,E\text{-triene; activity} & = 100 \\
\text{Z,Z,E\text{-triene; activity}} & < 2 \\
\text{Z,E,Z\text{-triene; activity}} & < 2 \\
\text{E,E,E\text{-triene}} & = 40
\end{align*}
\]

Elimination reactions and stereoselectivity

Unfortunately, most elimination reactions (Chapter 17) offer little control over the geometry of the product: treating sec-butanol in acid, for example, gives mainly the more substituted 2-butene, but as a 3:1 mixture of geometrical isomers. But there are some important exceptions. If the product has the double bond inside a ring of less than eight members, it has to be a \(cis\) double bond. Examples include the simple dehydration of a cyclopentanol and an intramolecular aldol reaction. The six-membered ring is formed before the dehydration step.

But how can we use elimination reactions to give single geometrical isomers of open-chain compounds? These reactions fall into four main classes, and we shall look at each in turn before summarizing the most important methods at the end of the chapter.

- Ways of making single geometrical isomers of double bonds
  1. Using the fact that only one geometrical isomer is possible (for example, a \(cis\) double bond in a six-membered ring).
  2. The geometrical isomers are in equilibrium and the more stable (usually \(E\)) is formed.
  3. The reaction is stereoselective and the \(E\) alkene or the \(Z\) alkene is formed as the main product by kinetic control.
  4. The reaction is stereospecific and the alkene geometry depends on the stereochemistry of the starting materials and the mechanism of the reaction.

Exploiting cyclic compounds

You may think that this method is rather too trivial to be called a method for controlling the geometry of double bonds, as it’s only of any use for making cyclic alkenes. Well, chemists are more ingenious than that! It is not necessary to have an all-carbon ring to preserve the \(cis\) geometry of a double bond. Lactones (cyclic esters) and cyclic anhydrides are useful too.
A double bond in a five- or six-membered compound must have a cis configuration and compounds like these are readily made. Dehydration of this hydroxylactone can give only a cis double bond and ring-opening with a nucleophile (alcohol, hydroxide, amine) gives an open-chain compound also with a cis double bond.

E J Corey used a similar idea to make the insect hormone we introduced on p. 678. He realized that the essential Z double bond would be easy to make if he were to start with a cyclic molecule (in which only cis double bonds are possible) that could be ring-opened to the compound he needed. This is how he did it.

Birch reduction (Chapter 23, p. 542) of a simple aromatic ether generated two cis double bonds. The more reactive (because it is more electron-rich) of these reacts with ozone to give an aldehyde-ester in which the Z geometry is preserved. NaBH₄ reduces the aldehyde group to a hydroxyl group, which needs to be got rid of: a good way to do this is to tosylate and reduce with LiAlH₄, which substitutes H for OTs. The LiAlH₄ also does the job of reducing the ester to an alcohol, giving the Z-configured compound that Corey needed.

**Equilibration of alkenes**

Acyclic E alkenes are usually more stable than acyclic Z alkenes because they are less sterically hindered. Yet Z alkenes do not spontaneously convert to E alkenes because the π bond prevents free rotation: the energy required to break the π bond is about 260 kJ mol⁻¹ (rotation about a σ bond requires about 10 kJ mol⁻¹). You may therefore find the following result surprising. Dimethyl maleate is easily made by refluxing maleic anhydride in methanol with an acid catalyst. If the product is isolated straight away, a liquid boiling at 199–202 °C is obtained. This is dimethyl maleate. However, if the product is left to stand, crystals of dimethyl fumarate (the E isomer of dimethyl maleate) form. How has the geometry been inverted so easily?

A clue is that the process is accelerated enormously by a trace of amine. Michael addition of this amine, or of methanol, or any other nucleophile, provides a chemical mechanism by which the π bond can be broken. There is free rotation in the intermediate, and re-elimination of the nucleophile can give either E or Z alkene. The greater stability and crystallinity of the E alkene means that it dominates the equilibrium. Michael addition therefore provides a mechanism for the equilibration of Z alkenes to E alkenes.

**Double bonds in rings**

The smallest stable ring that can contain a trans double bond is cyclooctene—trans-cycloheptene can exist but is very unstable.

**Nomenclature alert**

Beware! The terms cis and trans do not always translate directly into Z and E. Consider the preparation of an enamine from cyclohexanone, which forms a double bond that you’d probably call cis (it’s in a ring). But applying the rigorous rules laid down for E/Z nomenclature (p. 405), it is E. The same is true for the green double bond in the Birch reduction product above. As with the useful terms syn and anti (Chapter 14), there are no rigid rules for deciding whether a double bond is cis or trans. So there must be a diagram to make things clear if you use cis and trans.
Similar mechanisms account for the double bond geometry obtained in aldol reactions followed by dehydration to give α,β-unsaturated carbonyl compounds. Any Z alkene that is formed is equilibrated to E by reversible Michael addition during the reaction. The two examples which follow illustrate how effective this method is.

**Equilibration of non-conjugated alkenes**

Iodine will add reversibly not only to Michael acceptors but also to most other alkenes. It can therefore be a useful reagent for equilibrating double bond geometrical isomers.

Some Japanese chemists needed the E,E diene below for a synthesis of a neurotoxic compound that they had isolated from poison dart frogs. Unfortunately, their synthesis (which used a Wittig reaction—described in detail later in this chapter) gave only 4:1 E selectivity at one of the double bonds. To produce pure E,E diene, they equilibrated the E,Z diene to E,E by treating with iodine and irradiating with a sun-lamp.

**Using light to make Z alkenes from E alkenes**

Light allows the interconversion of the two isomers of an alkene by promoting a π electron into the π* orbital and transiently breaking the π bond, but the way light favours formation of the Z isomer is rather subtle. One difference between cis and trans alkenes is that the trans alkenes usually absorb light better than the cis alkenes—they absorb light of a higher wavelength and they absorb more of it, particularly when conjugated with carbonyl groups. Steric hindrance forces the cis alkene to twist about the σ bond joining the alkene to the carbonyl group and conjugation is then less efficient. In a mixture of E and Z alkenes, the E alkene is more prone to isomerization by light, so the Z isomer builds up in the mixture.

Here is an example. Aldol condensation of cyclohexanone and benzaldehyde gives pure E alkene for the reasons explained above. Irradiation with longer-wavelength UV light equilibrates this to the Z alkene in excellent yield.
It is not possible for the benzene ring and the enone system to be planar in the Z-enone and so they twist, making conjugation not as good as in the E-enone. Longer-wavelength light is absorbed only by the E-enone, which is continually equilibrated back to the excited state. Eventually, all the E-enone is converted to the Z-enone, which is not as efficiently excited by the light. The final mixture of E- and Z-enone is known as a 'photostationary state'.

The chemistry of vision

The human eye uses a cis alkene, 11-cis-retinal, to detect light, and a cis–trans isomerism reaction is at the heart of the chemical mechanism by which we see. The light-sensitive pigment in the cells of the retina is an imine, formed by reaction of 11-cis-retinal with a lysine residue of a protein, opsin. Absorption of light by the opsin–retinal compound, known as rhodopsin, promotes one of the electrons in the conjugated polyene system to an antibonding orbital. Free rotation in this excited state allows the cis double bond to isomerize to trans, and the conformational changes in the protein molecule that result trigger a cascade of reactions that ultimately leads to a nerve signal being sent to the brain.

E and Z alkenes can be made by stereoselective addition to alkynes

Alkenes can be made from alkynes by reduction or addition, and under the right conditions either the Z double bond or the E double bond can be formed stereoselectively.

Z-selective reduction of alkynes using Lindlar’s catalyst

The Z alkene below was needed pure for studies on the mechanism of a rearrangement reaction. In Chapter 23 you met catalytic hydrogenation as a means of reducing alkenes to alkanes,
and we introduced Lindlar’s catalyst (palladium and lead acetate on a support of calcium carbonate) as a means of controlling chemoselectivity so that alkynes could be reduced to alkenes. What we did not emphasize then was that the two hydrogen atoms add to the alkyne in a syn fashion and the alkene produced is a Z alkene. The stereoselectivity arises because two hydrogen atoms, bound to the catalyst, are delivered simultaneously to the alkyne.

The compound below is the pheromone of a destructive beetle. The synthetic pheromone can be used to trap the beetles, but it is active only as the Z isomer. Reduction of the alkyne with the Lindlar catalyst gives pure Z isomer, while the alternative way of making Z alkenes, the Wittig reaction, gives significant amounts of the E isomer.

**E-selective reduction of alkynes using sodium in liquid ammonia**

The best way of ensuring anti addition of hydrogen across any triple bond is to treat the alkyne with sodium in liquid ammonia.

The sodium donates an electron to the LUMO of the triple bond (one of the two orthogonal π* orbitals). The resulting radical anion can pick up a proton from the ammonia solution to give a vinyl radical. A second electron, supplied again by the sodium, gives an anion that can adopt the more stable trans geometry. A final proton quench by a second molecule of ammonia or by an added proton source (t-butanol is often used, as in the Birch reduction) forms the E alkene.

An alternative, and more widely used, method is to reduce alkynes with LiAlH₄ or the related reducing agent known as RedAl. This reaction works only if there is a hydroxy or an ether functional group near to the alkyne because it relies on delivery of the reducing agent to the triple bond through complexation to this oxygen atom.

Making alkenes by addition to alkynes offers two distinct advantages. Firstly, the starting materials can often be made straightforwardly by alkylation of alkynyl anions. Secondly, the same alkyne can be used to make either E or Z alkene. In some early work on sphingosine (a constituent of cell membranes), some Swiss chemists needed to make both E and Z
isomers of the naturally occurring compound. This was an easy task once they had made the alkyne.

\[
\begin{align*}
\text{OH} & & \text{NH}_2 \\
\text{R} & & \text{LiAlH}_4 \\
& & \text{sphingosine, 85\% yield, >98\% E}
\end{align*}
\]

Earlier in this chapter you were introduced to the significance of geometrically pure vinyl silanes, which can act as precursors to other alkenes. Controlled reduction of alkynyl silanes gives the corresponding vinyl silanes, with the method of reduction dictating the stereochemistry. Lindlar hydrogenation adds a molecule of hydrogen across the alkyne in a \textit{cis} fashion to produce the \textit{Z}-vinyl silane. RedAl reduction of a propargylic alcohol leads instead to the \textit{E} isomer.

The mechanism of the aluminium hydride reductions with LiAlH\(_4\) or RedAl involve a \textit{trans} hydroalumination helped by coordination of Al to the triple bond and external nucleophilic attack. The regioselectivity of the hydroalumination is again determined by silicon: the electrophilic Al attacks the alkyne on the carbon bearing the silyl group (the \textit{ipso} carbon).

\section*{Addition of nucleophiles to alkenes}

This rarer, and rather surprising, approach to \textit{Z} alkenes can give excellent results, particularly in the addition of nucleophiles to butadiyne. The base-catalysed addition of methanol gives an excellent yield of \textit{Z}-1-methoxybut-1-en-3-yne. This reaction is so easy to do that the product is available commercially. Notice that methanol adds once only: you would not expect nucleophiles to add to a simple alkyne and it is the conjugation that makes addition possible.

\[\text{Me}_3\text{Si} \equiv \text{OH} \quad 1. \text{Red Al}^\oplus \quad \text{ligand exchange} \quad \text{Me}_3\text{Si} \equiv \text{OH} \quad 2. \text{H}_2\text{O}^+ \]

Methoxide ion adds to one of the alkyynes to give a conjugated anion. The anion is linear with the negative charge delocalized into the second alkyne. The charge is therefore in a \textit{p} orbital in the plane of the molecule, with a second conjugated \textit{\pi} system oriented at right angles to the plane of the molecule.
When the anion reacts with a molecule of methanol, protonation occurs on the lobe of the p orbital away from the MeO group and the Z alkene is formed.

**Predominantly E alkenes can be formed by stereoselective elimination reactions**

In Chapter 17 you saw that E1 elimination reactions usually give mainly E alkenes (there's an example earlier in this chapter) because the transition state leading to an E double bond is lower in energy than that leading to a Z double bond. In other words, E1 reactions are stereoselective, and their stereoselectivity is **kinetically controlled**. E2 reactions are similar if there is a choice of protons that can be removed: the E alkene is preferred, but a mixture is still formed. Again, this is kinetic control.

Both stereo- and regioselectivity are usually better in E1cB reactions, such as the opening of this unsaturated lactone in base. The double bond inside the ring remains Z but the new one, formed as the ring opens, prefers the E geometry. The transition state for the elimination step already looks like the product and prefers the E geometry for simple steric reasons.

**Sulfoxide elimination—oxidation to enones**

Sulfoxides occupy a useful and interesting part of the middle ground between sulfides and sulfones—they are weakly nucleophilic, like sulfides (and can be alkylated with methyl
iodide to give sulfoxonium salts, as we saw on p. 667), but at the same time they stabilize anions almost as well as sulfones. They are easily made by controlled oxidation of sulfides and the chart below gives the main ways to get from sulfides to the two oxidized functional groups.

Sulfoxides can be used to make alkenes stereoselectively because sulfoxides next to electron-withdrawing or conjugating groups are unstable on heating, decomposing by an elimination process. The rather unstable phenylsulfenic acid (PhSOH) is eliminated and the reaction occurs partly because of the creation of conjugation and partly because PhSOH decomposes to volatile products. The starting material was made from cycloheptanone by sulfenylation of its enolate followed by oxidation.

The elimination follows a type of mechanism we call a pericyclic reaction. Once you have read Chapter 34 you should be able to identify the reaction as a reverse cycloaddition, but for now you can just think of it as an elimination in which the proton is removed by the leaving group. The alkene product in this case is in a seven-membered ring—it has to be cis.

This reaction provides a useful way of introducing a double bond next to a carbonyl group. Here it is in a synthesis of the Queen Bee Substance (the compound fed by the workers to those bee larvae destined to become queens). The compound is also a pheromone of the termite and is used to trap these destructive pests. The sulfur is introduced by reacting the enolate of the ester with the sulfur electrophile MeSSMe. Next, the protecting group is removed with acid, and the sulfide is oxidized to the sulfoxide with sodium periodate (NaIO₄) ready for elimination. Heating to 110°C then gives the Queen Bee Substance in 86% yield.

This elimination takes place more easily still when sulfur is replaced by a selenium—PhSe groups can be introduced by the same method, and oxidized to selenoxides with m-CPBA at
low temperature. The selenoxides are rarely isolated because the elimination takes place rapidly at room temperature.

The Julia olefination is regiospecific and connective

Sulfoxide eliminations are a valuable way of introducing a double bond to an already intact carbon skeleton. The alkene synthesis we are about to show you is also based on sulfur chemistry, but is connective— the alkene is formed by joining together two separate fragments. It is called the Julia olefination and is probably the most important application of the sulfone-stabilized anions you saw earlier in the chapter. Only the alkene shown is formed, with the double bond joining the two carbons that carried the PhSO2 and PhCO2 groups. This elimination is promoted by a reducing agent, traditionally sodium amalgam (a solution of sodium metal in mercury) and works for a variety of compounds providing they have a phenylsulfonyl group adjacent to a leaving group.

Common leaving groups are carboxylates such as acetate or benzoate, and the starting materials are very easily made. The sulfone-stabilized anion adds to aldehydes and a simple esterification step, which can be done in the same reaction vessel, introduces the acetate or benzoate group. This is how the starting material for the elimination above was made.

The Julia olefination is stereoselective

Here are the results of a few simple Julia olefinations. Notice that deprotonations can be with BuLi or EtMgBr and that the acylation step works with acetic anhydride or with benzoyl chloride. As you can see, they are all highly stereoselective for the $E$ isomer, and the Julia olefination is one of the most important ways of making $E$ double bonds connectively.
The reason for the $E$ selectivity lies in the mechanism of the elimination. The details are not fully clear, but the first step, under the basic conditions of the reduction, appears to be the elimination of the acetate or benzoate ester to give a vinyl sulfone.

The stereochemistry of the vinyl sulfone does not matter because it is immediately reduced by an electron from sodium to give a vinyl radical. Much as you saw above, in the Birch reduction of alkynes, the vinyl radical collects a second electron and becomes a vinyl anion, which chooses to adopt the more stable $E$ configuration before being protonated to give the predominantly $E$ alkene.

We know that there must be an anion intermediate because the elimination is not stereospecific—in other words, whichever diastereoisomer of the starting material you use (all of the examples in this section have been mixtures of diastereoisomers) you always get the $E$ alkene product.

**The one-step Julia olefination**

The Julia reaction is remarkably versatile but it does need three steps to make the alkene: addition, acylation, and reduction. A more recent version of the reaction cuts this down to one by using not a phenylsulfone but instead a sulfone carrying an electron-deficient heterocycle, for example a tetrazole. The anion of the sulfone is made with a strong base (here potassium hexamethyldisilazide, KHMDS—see p. 635) and is added to an aldehyde to give an alkene directly.

The elimination works because after the addition to the aldehyde, the alkoxide that is formed makes itself into a leaving group by grabbing the heterocyclic ring from the sulfur.

The final elimination is driven by loss of $\text{SO}_2$, and typically gives an $E$ alkene, although by choosing carefully the base and solvent the selectivity can be tuned to give predominantly $Z$. 
Stereospecific eliminations can give pure single isomers of alkenes

You met a stereospecific elimination in Chapter 17. The requirement for the H and the Br to be anti-periplanar in the E2 transition state meant that the two diastereoisomers of this alkyl bromide eliminated to alkenes with different double bond geometries (p. 396).

However, reactions like this are of limited use—their success relies on the base’s lack of choice of protons to attack. Logic dictates that only trisubstituted double bonds can be made stereospecifically in this way: the reaction must not have a choice of hydrogen atoms or an E alkene will result stereoselectively (as in the example on p. 684). The answer is, of course, to move away from eliminations involving H, and we can do this by returning to the Peterson elimination, which you met on p. 671.

The Peterson reaction is stereospecific

The stereospecificity of this elimination involving silicon arises because it is an E2 elimination proceeding via an anti-periplanar transition state. In principle, it can therefore be used to make single geometrical isomers of alkenes, the geometry depending on the relative stereochemistry of the starting material. However, this use of the Peterson reaction is limited by difficulties in making diastereoisomerically pure starting materials.

There is another, complementary, version of the Peterson reaction that uses base to promote the elimination. The starting materials are the same as for the acid-promoted Peterson reaction. When base (such as sodium hydride or potassium hydride) is added, the hydroxyl group is deprotonated and the oxyanion attacks the silicon atom intramolecularly. Elimination takes

Interactive mechanism for stereospecific E2

Interactive mechanism for stereospecific Peterson elimination
place this time via a \textit{syn-periplanar} transition state—it has to because the oxygen and the silicon are now bonded together, and it is the strength of this bond that drives the elimination forward.

The two versions of the Peterson reaction give opposite geometrical isomers from the same diastereoisomer of the starting material, so from any single diastereoisomer of hydroxy silane we can make either geometrical isomer of alkene product by choosing whether to use acid or base. The problem is still making those single diastereoisomers!

In Chapter 17 you saw that anti-periplanar transition states are usually preferred for elimination reactions because this alignment provides the best opportunity for good overlap between the orbitals involved. Syn-periplanar transition states can, however, also lead to elimination—and the base-promoted Peterson reaction should remind you of the Wittig reaction, which you first met in Chapter 11, with its four-membered cyclic intermediate. It is with the Wittig reaction, and a detailed discussion of its stereoselectivity, that we now finish this chapter.

\textbf{Perhaps the most important way of making alkenes—the Wittig reaction}

The Wittig reaction is another member of the class we have been talking about—it’s an elimination that does not involve loss of H. You met it in Chapter 11, where we gave a brief outline of its mechanism.

Conceptually, the Wittig reaction is like the base-promoted Peterson reaction: it is a \textit{syn} elimination, driven by the strength of an oxygen–heteroatom bond, although in this case the heteroatom is phosphorus. But the elimination step of the Wittig reaction occurs only from an intermediate and not from isolated starting materials. This intermediate is made \textit{in situ} in the reaction and decomposes spontaneously: the Wittig reaction is therefore another connective alkene-forming reaction, but its simplicity makes it more widely used than the Julia or Peterson reactions.

To understand the details of the reaction, we must start at the beginning. Phosphorus atoms, especially those that are positively charged or that carry electronegative substituents, can increase the acidity of protons adjacent to them on the carbon skeleton. Phosphonium salts (made in a manner analogous to the formation of ammonium salts from amines, in other words by reaction of an alkyl halide with a phosphine) can therefore be deprotonated by a moderately strong base to give a species known as an \textit{ylid} (sometimes spelled \textit{ylide}), carrying (formally) a positive and a negative charge on adjacent atoms. Ylids can alternatively be represented as doubly bonded species, called \textit{phosphoranes}.

Phosphorus is like sulfur in this regard: you can compare the phosphonium ylid with the sulfonyl-stabilized anions you met earlier.
Ylids can be isolated, but are usually used in reactions immediately they are formed. They are nucleophilic species that will attack the carbonyl groups of aldehydes or ketones, generating the four-membered ring oxaphosphetane intermediates. Oxaphosphetanes are unstable: they undergo elimination to give an alkene (65% yield for this particular example) with a phosphine oxide as a by-product. The phosphorus–oxygen double bond is extremely strong and it is this that drives the whole reaction forward.

\[ \text{Ph}_3\text{P} = \text{O} \rightarrow \text{alkene} 65\% \text{ yield} \]

**Stereoselectivity in the Wittig reaction depends on the ylid**

The Wittig reactions below were all used in the synthesis of natural products. You will notice that some reactions are Z selective and some are E selective. Look closer, and you see that the stereoselectivity is dependent on the nature of the substituent on the carbon atom of the ylid.

We can divide ylids into two types: those with conjugating or anion-stabilizing substituents adjacent to the negative charge (such as carbonyl groups) and those without. We call the first sort stabilized ylids because the negative charge is stabilized not only by the phosphorus atom but by the adjacent functional group—we can draw an alternative enolate-type structure to represent this extra stabilization. The rest we call unstabilized ylids.

---

In Chapter 11, to help you understand the reaction, we showed the addition to the carbonyl group to make the four-membered ring taking place in two steps. These steps are probably in fact concerted (they both happen at the same time), and a better representation of the reaction is the single-step formation of the four-membered ring shown here.

[Diagram showing the concerted reaction]

---

**The stereochemistry of the Wittig reaction**

The general rule is:

- with stabilized ylids the Wittig reaction is E selective
- with unstabilized ylids the Wittig reaction is Z selective.

**The Z-selective Wittig reaction**

The Z selectivity observed with simple alkyl R groups is nicely complementary to the E selectivity observed in the Julia olefination. This complementarity was exploited by some chemists who wanted to make isomers of capsaicin (the compound that gives chilli peppers...
their ‘hotness’) to follow up suggestions that capsaicin might be carcinogenic. The key intermediates in the synthesis of the $E$ and $Z$ isomers of capsaicin were the $E$ and $Z$ unsaturated esters shown below. By using a Wittig reaction with an unstabilized ylid it was possible to make the $Z$ isomer selectively, whilst the Julia olefination gave the $E$ isomer.

How can the $Z$ selectivity in Wittig reactions of unstabilized ylids be explained? We have a more complex situation in this reaction than we had for the other eliminations we considered because we have two separate processes to consider: formation of the oxaphosphetane and decomposition of the oxaphosphetane to the alkene. The elimination step is the easier one to explain—it is stereospecific, with the oxygen and phosphorus departing in a syn-periplanar transition state. Addition of the ylid to the aldehyde can, in principle, produce two diastereoisomers of the intermediate oxaphosphetane. Provided that this step is irreversible, then the stereospecificity of the elimination step means that the ratio of the final alkene geometrical isomers will reflect the stereoselectivity of this addition step.

When R is not conjugating or anion-stabilizing, the syn diastereoisomer of the oxaphosphetane is formed preferentially, and the predominantly $Z$ alkene that results reflects this. The $Z$-selective Wittig reaction therefore consists of a stereoselective first step, to form the syn oxaphosphetane, followed by a stereospecific elimination from this intermediate to give a $Z$ alkene.

The $E$-selective Wittig reaction

Stabilized ylids, that is ylids whose anion is stabilized by further conjugation, usually with a carbonyl group, give $E$ alkenes on reaction with aldehydes.
These stabilized ylids really are stable—this one, for example, can be recrystallized from water and the ylid is more stable than the phosphonium salt from which it might be made. This stability means though that they are not very reactive, and often it is better not to use the phosphonium salt but a phosphonate instead.

Phosphonate esters can be deprotonated with sodium hydride or alkoxide anions to give enolate-type anions that react well with aldehydes or ketones to give $E$ alkenes. Alkene-forming reactions with phosphonates are called Horner–Wadsworth–Emmons (or Horner–Emmons, Wadsworth–Emmons, or even Horner–Wittig) reactions. This example is a reaction that was used by some Japanese chemists in the synthesis of polyzonimine, a natural insect repellent produced by millipedes.

The synthesis below offers a nice illustration of the contrasting selectivity of the two classes of Wittig reagent. The female silkworm moth attracts mates by producing a pheromone known as bombykol. Bombykol is an $E,Z$-diene, and in this synthesis two successive Wittig reactions use first a stabilized and second an unstabilized ylid to control the stereochemistry of the product.

So why is there a change to $E$ stereoselectivity when the ylid is stabilized? Again, the details are still unclear, and there are several possible explanations. Here we give one which is gaining ground, supported by recent experimental and computational evidence. It seems that, as with unstabilized ylids, the stereochemistry of the alkene product is determined by the stereochemistry of the intermediate oxaphosphetane, which with stabilized ylids must be anti.

It used to be thought that the formation of the anti oxaphosphetane was under thermodynamic control, but it now seems likely that it too is formed stereoselectively under kinetic control. The difference from the alkyl-substituted unstabilized ylids lies in the repulsion experienced between the polarized $\text{C}=\text{O}$ bond of the aldehyde and the electronegative stabilizing group shown here as an ester $\text{CO}_2\text{R}$. As the four-membered ring flattens out, the $\text{CO}_2\text{R}$ and Ph groups end up on opposite sides of the four-membered ring.
To conclude

In this chapter we have dealt for the first time with the problem of producing compounds as single stereoisomers—the stereoisomers concerned were geometrical isomers of alkenes. In future chapters we shall look in more detail at making stereoisomers, but we shall move out of two dimensions into three and consider reactions that exhibit diastereoselectivity and enantioselectivity. Methods for controlling stereochemistry in two and in three dimensions are closely related: single diastereoisomers are often made by addition reactions of single geometrical isomers of double bonds and, as you saw with the Peterson and Wittig reactions, single diastereoisomers can lead stereospecifically to single geometrical isomers.

Creative chemistry

Chemistry is above all a creative science. Nearly all that you have learned so far in this book has had one underlying aim: to teach you how to make molecules. This is after all what most chemists do, for whatever reason. Small amounts of many drugs can be isolated from plants or marine animals; much greater quantities are made by chemists in laboratories. A limited range of dyes can be extracted from plants; many more vivid and permanent ones are made by chemists in the laboratory. Synthetic polymers, created by chemists, have replaced more expensive and less durable alternatives like rubber. Despite the bad press it has received, the use of PVC as insulating material for electric wires has prevented numerous fires and saved many lives. Food is healthier and people live longer because well-designed and controlled pesticides allow agriculture to supply copious quantities of disease-free food to the shelves of our shops, markets, and supermarkets. Most of the improvements in the quality of life over the last 50 to 100 years can be traced to new molecules created by chemists. But, faced with the challenge of making a new compound, how do chemists go about deciding how to make it?

Synthetic planning starts with the product, which is fixed and unchangeable, and works backwards towards the starting materials. This process is called retrosynthesis, and the art of planning the synthesis of a target molecule is called retrosynthetic analysis. The aim of this chapter is to introduce you to the principles of retrosynthetic analysis: once you have read and understood it you will be well on the way to designing your own organic syntheses.

Retrosynthetic analysis: synthesis backwards

Most of the chemistry you have learned so far has concentrated on reactions (questions like ‘What do you need to add to X to get Y?’) or on products (questions like ‘What will happen if X and Y react together?’). Now we’re looking at starting materials (questions like ‘What X and Y do you need to react together to make Z?’). We’re looking at reactions in reverse, and we have a special symbol for a reverse reaction called a retrosynthetic arrow (the ‘implies’ arrow from logic). A scheme with a retrosynthetic arrow (margin) means ‘Z could be made from X plus Y’.

Online support. The icon in the margin indicates that accompanying interactive resources are provided online to help your understanding: just type www.chemtube3d.com/clayden/123 into your browser, replacing 123 with the number of the page where you see the icon. For pages linking to more than one resource, type 123-1, 123-2 etc. (replacing 123 with the page number) for access to successive links.
Here's a very simple first example. This compound is used as an insect repellent. As it's an ester, we know that it can be made from alcohol plus acyl chloride, and we can represent this using a retrosynthetic arrow.

\[
\text{Ph} \quad \text{O} \quad \text{Ph} \quad \text{ester} \quad \text{Ph} \quad \text{O} \quad \text{Cl} + \quad \text{Ph} \quad \text{OH} \quad \text{acyl chloride}
\]

The aromatic amide amelfolide is a cardiac antiarrhythmic agent. Because we see that it is an amide, we know that it can be made quite simply from \( p \)-nitrobenzoyl chloride and 2,6-dimethylaniline—again, we can represent this using a retrosynthetic arrow. Mentally breaking a molecule into its component parts like this is known as disconnection, and it's helpful to indicate the site of the disconnection with a wiggly line as we have here.

**Disconnections must correspond to known, reliable reactions**

The chemists who first made amelfolide chose to make it from an amine and an acyl chloride because they knew that this reaction, a standard way of making an amide, had a very good chance of success. They chose to disconnect the C–N bond because this disconnection corresponds to a reliable reaction in a way that no other possible disconnection of this molecule does.

Now that you've seen the principle of retrosynthetic analysis at work, you should be able to suggest a reasonable disconnection of the compound in the margin, known as daminozide. You probably spotted immediately that daminozide is again an amide, so the best disconnection is the C–N bond, which could take us back to acyl chloride and dimethylhydrazine. This time we've written ‘C–N amide’ above the retrosynthetic arrow as a reminder of why we've made the disconnection and we advise you to follow this practice.

Now, in fact, there is a problem with this acyl chloride—it would be unstable as it can cyclize to an anhydride. But this poses no problem for the synthesis of daminozide—we could just use the anhydride instead, since the reaction should be just as reliable. A better retrosynthesis therefore gives the anhydride and indeed this is how daminozide is made.

**Synthons are idealized reagents**

In the synthesis of daminozide an anhydride is used out of necessity rather than out of choice, but it often turns out that there are several alternative reagents all corresponding to
the same disconnection. Paracetamol, for example, is an amide that can be disconnected either to amine + acyl chloride or to amine + anhydride.

\[
\text{paracetamol} \quad \rightarrow \quad \text{amine} + \text{acyl chloride or anhydride.}
\]

Which reagent is best can often only be determined by experimentation—commercially, paracetamol is made from para-aminophenol and acetic anhydride largely because the by-product, acetic acid, is easier to handle than HCl. In a retrosynthetic analysis, we don’t really want to be bothered by this sort of decision, which is best made later, so it’s useful to have a single way of representing the key attributes of alternative reagents. We can depict both anhydride and acyl chloride in this scheme as an ‘idealized reagent’—an electrophilic acetyl group MeCO⁺.

We call such idealized reagents synths. Synthons are fragments of molecules with an associated polarity (represented by a ‘+’ or ‘−’) which stand for the reagents we are going to use in the forward synthesis. They are not themselves reagents, although they may occasionally turn out to be intermediates along the reaction pathway. By disconnecting bonds to synthons rather than to actual reagents we can indicate the polarity of the bond-forming reaction we are going to use without having to specify details of the reagents.

We can apply these ideas to the synthesis of the herbicide 2,4-D (2,4-dichlorophenoxyacetic acid). The most reasonable disconnection of an ether is the C–O bond because we know that ethers can be made from alkyl halides by substitution with an alkoxide anion. We don’t at this stage need to decide exactly which alkyl halide or alkoxide to use, so we just write the synthons.

Once the retrosynthetic analysis is done, we can go back and use our knowledge of chemistry to think of reagents corresponding to these synthons. Here, for example, we should certainly choose the anion of the phenol as the nucleophile and some functionalized acetic acid molecule with a leaving group in the α position.

We can then write out a suggested synthesis in full from start to finish. It isn’t reasonable to try to predict exact conditions for a reaction: to do that you would need to conduct a thorough search of the chemical literature and do some experiments. However, all of the syntheses in this chapter are real examples and we shall often give full details of conditions to help you become familiar with them.
Choosing a disconnection

The hardest task in designing a retrosynthetic analysis is spotting where to make the disconnections. We shall offer some guidelines to help you, but the best way to learn is through experience and practice. The overall aim of retrosynthetic analysis is to get back to starting materials that are available from chemical suppliers, and to do this as efficiently as possible.

**Guideline 1**

Disconnections must correspond to known, reliable reactions.

We have already mentioned that disconnections must correspond to known reliable reactions and it’s the most important thing to bear in mind when working out a retrosynthesis. When we disconnected the ether 2,4-D we chose to disconnect next to the oxygen atom because we know about the synthesis of ethers. We chose not to disconnect on the aryl side of the oxygen atom because we know of no reliable reaction corresponding to nucleophilic attack of an alcohol on an unactivated aromatic ring.

![Bad choice of disconnection: no reliable equivalent reaction](image)

**Guideline 2**

For compounds consisting of two parts joined by a heteroatom, disconnect next to the heteroatom.

In all the retrosynthetic analyses you’ve seen so far there is a heteroatom (N or O) joining the rest of the molecule together, and in each case we made the disconnection next to that N or O. This guideline works for esters, amides, ethers, amines, acetals, sulfides, and so on because these compounds are often made by a substitution reaction. Chlorbenside is used to kill ticks and mites. Using Guideline 2 we can suggest a disconnection next to the sulfur atom; using Guideline 1 we know that we must disconnect on the alkyl and not on the aryl side.

![Chlorbenside: retrosynthetic analysis](image)

We can now suggest reagents corresponding to the synthons and propose a synthetic scheme.
The next example is the ethyl ester of, and precursor to, cetaben, a drug that can be used to lower blood lipid levels. It is an amine, so we disconnect next to the nitrogen atom.

The alkyl bromide is available but we shall need to make the aromatic amino-ester and the best disconnection for an ester is the C–O bond between the carbonyl group and the esterifying group.

We have now designed a two-step synthesis of our target molecule, and this is how it is carried out.

Multiple step syntheses: avoid chemoselectivity problems

The next compound was an intermediate in the synthesis of the potential anti-obesity drug ICI-D7114. You can spot that, with two ethers and an amine functional group, it requires several disconnections to take it back to simple compounds. The question is, which do we do first? One way to solve the problem is to write down all the possibilities and see which looks best. Here there are four reasonable disconnections: one at each of the ether groups (a and b) or on either side of the amine (c and d).
Both \(a\) and \(b\) pose problems of chemoselectivity as it would be hard to alkylate the phenol in the presence of the basic nitrogen atom. Between \(c\) and \(d\), \(c\) appears to be the better choice because the next disconnection after \(d\) will have to be an alkylation of O in the presence of an NH\(_2\) group. To avoid chemoselectivity problems like this, we want to try to introduce reactive groups late in the synthesis. In terms of retrosynthetic analysis, then, we can formulate another guideline.

- **Guideline 3**

  Consider alternative disconnections and choose routes that avoid chemoselectivity problems—often this means disconnecting reactive groups first.

This guideline helps us in the next retrosynthetic step for the ICI-D7114 intermediate. Disconnection \(c\) gave us a compound with two ethers that might be disconnected further by disconnection \(e\) or \(f\).

Disconnection \(e\) requires alkylation of a compound that is itself an alkylation agent. Disconnection \(f\) is much more satisfactory and leads to a compound that is easily disconnected to 4-hydroxyphenol and 1,2-dibromoethane. Using Guideline 3, we can say that it’s best to disconnect the bromoethyl group \(f\) before the benzyl group \(g\) because the bromoethyl group is more reactive and more likely to cause problems of chemoselectivity.

**ICI-D7114 intermediate: synthesis**

Functional group interconversion

The antihypertensive drug ofornine contains an amide and an amine functional group, and we need to decide which to disconnect first. If we disconnect the secondary amine first \(b\), we will have chemoselectivity problems constructing the amide in the presence of the resulting NH\(_2\) group.

Yet disconnection \(a\), on the face of it, seems to pose an even greater problem because we now have to construct an amine in the presence of an acyl chloride! However, we shall want to make the acyl chloride from the carboxylic acid, which can then easily be disconnected to 2-aminobenzoic acid (anthranilic acid) and 4-chloropyridine.
The retrosynthetic transformation of an acyl chloride to a carboxylic acid is not really a disconnection because nothing is being disconnected. We call it instead a functional group interconversion, or FGI, as written above the retrosynthetic arrow. Functional group interconversions often aid disconnections because the sort of reactive functional groups (acyl chlorides, alkyl halides) we want in starting materials are not desirable in compounds to be disconnected because they pose chemoselectivity problems. They are also useful if the target molecule contains functional groups that are not easily disconnected.

By using an appropriate reagent or series of reagents, almost any functional group can be converted into any other. You should already have a fair grasp of reasonable functional group interconversions. They mostly fall into the categories of oxidations, reductions, and substitutions (Chapters 10, 11, 15, and 23).

**Amine synthesis using functional group interconversions**

The synthesis of amines poses a special problem because only in certain cases is the obvious disconnection successful.

The problem is that the product is usually more reactive than the starting material and there is a danger that multiple alkylation will take place.

The few successful examples you have seen so far in this chapter have been exceptions, for either steric or electronic reasons, and from now on we advise you to avoid disconnecting an amine in this way. Sometimes further alkylation is made unfavourable by the increased steric hindrance that would result: this is probably the case for the cetaben ethyl ester we made by this reaction.
If the alkylating agent contains an inductive electron-withdrawing group, the product may be less reactive than the starting material—benzylamine was only alkylated once by the alkyl bromide in the synthesis of ICI-D7114 on p. 699 because of the electron-withdrawing effect of the aryl group.

What are the alternatives? There are two main ones, and both involve functional group interconversion, with the reactive amine being converted to a less reactive derivative before disconnection. The first solution is to convert the amine to an amide and then disconnect that. The reduction of amide to amine is quite reliable, so the FGI is a reasonable one.

\[
\begin{align*}
\text{amines: retrosynthetic analysis 1} &
\end{align*}
\]

\[
\begin{align*}
\text{R}^1\text{H} & \xrightarrow{\text{FGI}} \text{R}^1\text{NH}_2\xrightarrow{\text{reduction}} \text{R}^1\text{NH}_2 + \text{Cl}\text{R}^2
\end{align*}
\]

\[

\end{align*}
\]

The second alternative is to convert to an imine, which can be disconnected to amine plus carbonyl compound. This approach is known as reductive amination and we discussed it in detail in Chapter 11.

\[
\begin{align*}
\text{amines: retrosynthetic analysis 2} &
\end{align*}
\]

\[
\begin{align*}
\text{R}^1\text{H} & \xrightarrow{\text{FGI}} \text{R}^1\text{NH}_2\xrightarrow{\text{reduction}} \text{R}^1\text{NH}_2 + \text{H}\text{R}^2
\end{align*}
\]

\[
\begin{align*}
\text{amines: synthesis 2 (reductive amination)} &
\end{align*}
\]

\[
\begin{align*}
\text{R}^1\text{NH}_2 + \text{H} + \text{O} & \xrightarrow{\text{H}^+ \text{cat.}} \text{R}^1\text{NH}_2 + \text{H} + \text{O} \xrightarrow{\text{NaBH}_4 \text{ or NaNBH}_3 \text{ or H}_2, \text{cat.}} \text{R}^1\text{NH}_2 + \text{H} + \text{O}
\end{align*}
\]

Ocftentanil is an opioid painkiller that lacks the addictive properties of morphine. Disconnection of the amide gives a secondary amine that we can convert to an imine for disconnection to a ketone plus 2-fluoroaniline.

\[
\begin{align*}
\text{ocfentanil: retrosynthetic analysis} &
\end{align*}
\]

\[
\begin{align*}
\text{Ph} \xrightarrow{\text{FGI}} \text{Ph} \xrightarrow{\text{reduction}} \text{Ph} \xrightarrow{\text{FGI}} \text{Ph} \xrightarrow{\text{reduction}} \text{Ph}
\end{align*}
\]

The synthesis is straightforward: a reductive amination followed by acylation of the only remaining NH group. The tertiary amine in the left-hand ring interferes with neither of these reactions.
There are several conceivable routes to the neuroactive drug fenfluramine—one analysis, which uses both the amide and the imine FGI methods, is shown below and this is the route used to make the drug. Notice that the oxime is used instead of the imine. N-unsubstituted imines are very unstable, and the much more stable—indeed isolable—oxime serves the same purpose. Oximes are generally reduced with LiAlH₄.

You should now be able to suggest a plausible analysis of the secondary amine terodilin. The structure is in the margin; write down a retrosynthetic analysis and suggested synthesis before looking at the actual synthesis below.

You should find yourself quite restricted in choice: the amide route clearly works only if there is a CH₂ group next to the nitrogen (this comes from the C=O reduction), so we have to use an imine.

In the synthesis of terodilin, it was not necessary to isolate the imine—reduction of imines is faster than reduction of ketones, so formation of the imine in the presence of a mild reducing agent (usually NaCNBH₃ or catalytic hydrogenation) can give the amine directly.

**Two-group disconnections are better than one-group disconnections**

This compound was needed for some research into the mechanisms of rearrangements. We can disconnect on either side of the ether oxygen atom, but (b) is much better because (a) does not correspond to a reliable reaction: it might be hard to control selective alkylation of the primary hydroxyl group in the presence of the secondary one.
You might think that the best reagent to use as the equivalent of the synthon B would be bromide C. Be more ingenious! A much better solution is to use the epoxide D. Nucleophilic attack on the less hindered terminal carbon atom of the epoxide gives us the type of compound we want, and this was how the target molecule was made.

In using the epoxide we have gone one step beyond all the disconnections we have talked about so far because we have used one functional group to help disconnect another—in other words, we noticed the alcohol adjacent to the ether we wanted to disconnect and managed to involve them both in the disconnection. Such disconnections are known as two-group disconnections, and you should always be on the look-out for opportunities of using them because they are an efficient way of getting back to simple starting materials. We call this epoxide disconnection a 1,2-disconnection because the two functional groups in the two-group disconnection are in a 1,2-relationship.

Drug molecules often have 1,2-related functional groups: 2-amino alcohols form one important class. Phenylpyridinol, for example, is a muscle relaxant. A simple two-group disconnection takes it straight back to 2-amino pyridine and styrene oxide.

Notice that we have written ‘1,2-diX’ above the arrow to show that it’s a two-group (‘diX’) disconnection—we’ve also numbered the carbon atoms in the starting material to show the 1,2-relationship. It may seem trivial in such a simple example, but it’s a useful part of the process of writing retrosynthetic analyses because it helps you to spot opportunities for making two-group disconnections.

1,2-Disconnections

The drug propranolol is a beta-blocker that reduces blood pressure and was once one of the top-selling drugs worldwide. It has two 1,2-relationships in its structure but it is best to disconnect the more reactive amine group first. The second disconnection can’t make use of an epoxide, but a simple ether disconnection takes us back to 1-naphthol and epichlorohydrin, a common starting material for this type of compound.
Moxnidazole is an antiparasitic drug, and our next target molecule is an important intermediate in its synthesis. The obvious first disconnection is of the carbamate group, revealing two 1,2-relationships. A 1,2-diX disconnection gives an epoxide that can be made by alkylation of morpholine with epichlorohydrin.

1,2-Disconnections with carbonyl compounds

Just as epoxides are useful reagents for synthon A, so α-halocarbonyl compounds are useful reagents for the carbonyl equivalent, synthon B. We can consider disconnection to this synthon to be a two-group disconnection because the α-halocarbonyl compounds are easily made by halogenation of a ketone, ester, or carboxylic acid (see Chapter 20) and the carbonyl group adjacent to the halide makes them extremely reactive electrophiles (Chapter 15).

Nafimidone is an anticonvulsant drug with an obvious two-group disconnection of this type. The α-chloroketone is simply made by chlorination, and substitution is rapid and efficient even with the weakly basic (Chapter 8) heterocycle imidazole.
The aldehyde below was needed by ICI when they were developing a thromboxane antagonist. Two-group disconnection gives a 2-halo-aldehyde that can be made from isobutyraldehyde.

ICI aldehyde: retrosynthetic analysis

![ICI aldehyde: retrosynthetic analysis](image)

The synthesis requires a normal bromination of a carbonyl compound in acid solution but the next step is a most unusual S$_2$2 reaction at a tertiary centre. This happens because of the activation by the aldehyde group (Chapter 15) and is further evidence that the functional groups must be thought of as working together in this type of synthesis.

ICI aldehyde: synthesis

![ICI aldehyde: synthesis](image)

1,3-Disconnections

In Chapter 22 you saw how α,β-unsaturated carbonyl compounds undergo conjugate additions—reactions like this:

![1,3-Disconnections](image)

Two-group 1,3-disconnections are therefore possible because they correspond to this forward reaction. These Michael acceptors have an electrophilic site two atoms away from the carbonyl group, and are therefore the reagents corresponding to this synthon.

![1,3-diX](image)

This type of reaction is available only when the alkene is conjugated to an electron-withdrawing group—usually carbonyl, but it can be nitro, cyanide, etc. (Chapter 22). This disconnection is available only at this oxidation level. We can do a two-group 1,3-disconnection on this sulfide, for example.

retrosynthetic analysis

![retrosynthetic analysis](image)

Remember that not all nucleophiles will successfully undergo Michael additions—you must bear this in mind when making a 1,3-disconnection of this type. Most reliable are those based on nitrogen, sulfur, and oxygen (Chapter 22). Our second example is an amine structurally similar to the ‘deadly nightshade’ drug, atropine, which has the ability to calm involuntary muscle movements. There is a 1,3-relationship between the amine and ketone functional groups, and 1,3-disconnection takes us back to piperidine and an unsaturated ketone.
To summarize...

Before we leave C–X disconnections and go on to look at C–C disconnections we should just review some important points. We suggested three guidelines for choosing disconnections and now that you have met the principle of two-group disconnections, we can add a fourth:

● **Guidelines for good disconnections**

1. Disconnections must correspond to known, reliable reactions.
2. For compounds consisting of two parts joined by a heteroatom, disconnect next to the heteroatom.
3. Consider alternative disconnections and choose routes that avoid chemoselectivity problems—often this means disconnecting reactive groups first.
4. Use two-group disconnections wherever possible.

Two-group disconnections reduce the complexity of a target molecule more efficiently than one-group disconnections, and you should always be on the look-out for them. You will meet more two-group disconnections in the next section, which deals with how to disconnect C–C bonds.

**C–C disconnections**

The disconnections we have made so far have all been of C–O, C–N, or C–S bonds, but, of course, the most important reactions in organic synthesis are those that build the carbon skeleton by forming C–C bonds. We can analyse C–C disconnections in much the same way as we’ve analysed C–X disconnections. Consider, for example, how you might make the simple compound in the margin, which is an intermediate in the synthesis of a carnation perfume.

The only functional group is the triple bond, and we shall want to use the chemistry of alkyne anions to show us where to disconnect. You know that alkylation of alkynes is a reliable reaction, so a sensible disconnection is next to the triple bond.

Alkynes are particularly valuable as synthetic intermediates because they can be reduced either to cis or to trans double bonds.
It’s often a good idea to start retrosynthetic analysis of target molecules containing isolated double bonds by considering FGI to the alkyne because C–C disconnections can then become quite easy. The cis-alkene below is an intermediate in the synthesis of a component of violet oil. FGI to the alkyne reveals two further disconnections that make use of alkyne alkylations. The reagent we need for the first of these is, of course, the epoxide as there is a 1,2-relationship between the OH group and the alkyne.

The next example is the pheromone of the pea-moth, and can be used to trap the insects. After disconnecting the ester, FGI on the trans double bond gives an alkyne.

Disconnection on either side of the alkyne leads us back to a bromo-alcohol alkylating agent. In the synthesis of the pheromone, it turned out to be best if the hydroxyl group was protected as its THP ether. You should be able to think of other alkylation-type reactions that you have met that proceed reliably and therefore provide a good basis for a disconnection—the alkylation of enolates of esters or ketones, for example (Chapter 25).

You met these reductions in Chapter 27.

There are, of course, many other ways of disconnecting double bonds: you are about to meet an important disconnection of double bonds conjugated with carbonyl groups. Chapter 27 covered the alternative methods available for making double bonds and controlling their stereochemistry.

Protecting groups were discussed in detail in Chapter 23 and THP is on p. 551.

### 1,2 C–C disconnections

This next ester was needed for a synthesis of the sedative rogletimide (see later for the full synthesis). The ethyl group is disconnected because it can be readily introduced by alkylation of the ester enolate.
We have labelled the disconnection ‘1,2 C–C’ because the new C–C bond is forming two atoms away from the carbonyl group. To spot disconnections of this sort, you need to look for alkyl groups in this 2-position.

Arildone is a drug that prevents polio and herpes simplex viruses from ‘unwrapping’ their DNA, and renders them harmless. It has just the structural characteristic you should be looking for: a branch next to a carbonyl group,

With two carbonyl groups, the alkylation should be particularly straightforward since we can use a base like methoxide. The ether disconnection is then immediately obvious. In the synthesis of arildone the alkyl iodide was used for the alkylation.

We introduced the chemistry of malonate esters in Chapters 20 and 25 as a useful way of controlling the enolization of carbonyl compounds. Alkylation followed by decarboxylation means that we can treat acetoacetate and malonate esters as equivalent for these synthons.

This unsaturated ketone is an important industrial precursor to β-carotene, vitamin A, and other similar molecules. Disconnection using the carbonyl group gives a synthon for which a good reagent will be acetoacetate.
This organophosphorus compound, belfosil, is a Ca\(^{2+}\) channel blocker. You haven’t met many phosphorus compounds yet, but you should be able to reason that a good disconnection will be the C–P bond by analogy with the sulfides you met earlier in the chapter. We could use bromide as a leaving group, but alkyl bromides are inconvenient to disconnect further, so we go back to the more versatile diol—in the forward synthesis we shall need a way of making the OH groups into good leaving groups. There is still no obvious disconnection of the diol, but FGI to the ester oxidation level reveals a malonate derivative.

\[
\text{PhO} \quad \text{P(OBu)}_2 \quad \text{C–P} \quad \text{FGI} \quad \text{reduction} \quad 1,2 \text{ C–C}
\]

In the synthesis, the diol was converted to the bis-tosylate (see Chapter 15 if you’ve forgotten about tosylates and mesylates) and combined with a phosphorus nucleophile.

\[
\text{belfosil: synthesis}
\]

Notice how we disconnected the phosphorus-based functional groups straight back to alcohols in the retrosynthetic analysis, and not, say, to alkyl halides. Oxygen-based functional groups (alcohols, aldehydes, ketones, esters, and acids) have one important property in common—versatility. They are easily converted into each other by oxidation and reduction, and into other groups by substitution. What is more, many of the C–C disconnections you will meet correspond to reactions of oxygen-based groups, and particularly carbonyl groups. Faced with an unusual functional group in a target molecule the best thing to do is convert it to an oxygen-based group at the same oxidation level—it usually makes subsequent C–C disconnections simpler. So we add a new guideline.

**Guideline 5**

*Convert to oxygen-based functional groups to facilitate C–C disconnections.*

In each of the cases you have met so far, we have used a functional group present in the molecule to help us to disconnect the C–C bond using a 1,2 C–C disconnection. You can look for 1,2 C–C disconnections in alkynes, carbonyl compounds, and alkylated aromatic rings. And, if the target isn’t a carbonyl compound, consider what would be possible if functional groups such as hydroxyl groups were converted to carbonyl groups (just as we did with belfosil).

**1.1 C–C disconnections**

All of these disconnections relied on the reaction of a carbon electrophile with a nucleophilic functional group. The alternative, reaction of a carbon nucleophile (such as a Grignard reagent) with an electrophilic functional group, allows us to do C–C disconnections on alcohols. For example, this compound, which has a fragrance reminiscent of lilac, is a useful perfume in soap because (unlike many other perfumes that are aldehydes or ketones) it is stable to alkali.
We look to the one functional group, the hydroxyl, to tell us where to disconnect, and disconnection next to the OH group gives two synthons for which sensible reagents are a Grignard reagent and acetone. The perfume is made from benzyl chloride and acetone in this way. Notice that we label these disconnections 1,1 C–C because the bond being disconnected is attached to the same carbon atom as the hydroxyl functional group.

This similar alcohol has a ‘peony-like fruity odour’ and could be disconnected in three ways.

Disconnection (c) leads back to a ketone, which is cheaply made starting from acetone and benzaldehyde, and this was the route that was chosen for the synthesis.

**Double disconnections can be a short cut**

Tertiary alcohols with two identical groups next to the hydroxyl group are often made by attack of two equivalents of a Grignard reagent on an ester. The synthesis of the antihistamine compound fenpiprane provides an example: the tertiary alcohol is a precursor to the drug and can be disconnected to ester + Grignard reagent because of the two Ph groups. The ester required has a 1,3 functional group relationship, and can be disconnected to amine plus Michael acceptor.

The fact that Grignard reagents add twice to esters means that disconnection of a ketone in this way is often not reliable because the Grignard reagent adds to the ketone.
An alternative is to first convert to the alcohol oxidation level, then disconnect. This was the method chosen for this starting material for the synthesis of chlorphedianol.

### Available starting materials

Although any of the three routes to the ‘fruity peony perfume’ on p. 710 would give an acceptable synthesis, the key factor in choosing route (c) was the ease of synthesis of the starting materials from available compounds. But how can you know which materials will be available? So far in this chapter we have avoided this question, and often our retrosynthetic analyses have been incomplete because the suggested starting materials must themselves be synthesized in the laboratory. From now on, however, we will take every analysis back to available starting materials to help you get a feel for what is, and is not, available.

The only way to be absolutely sure what you can buy is to look up a compound in a supplier’s catalogue, and this is what a chemist would do when assessing possible alternative synthetic routes. A good rule of thumb is that compounds with up to about six carbon atoms and with one functional group (alcohol, aldehyde, ketone, acid, amine, double bond, or alkyl halide) are usually available. This is less true for heavily branched compounds, but most straight-chain compounds with these functional groups are available up to eight or more carbon atoms. Cyclic compounds with one functional group from five-to-eight-membered are also available. Of course, many other compounds are available too, including some difunctional compounds. Here are a few of them.

- **acetoacetates**

```
O
R = H, Me, Et
```

- **malonates**

```
O
R = H, Me, Et
```

- **acrylates** (R = H); **methacrylates** (R = Me)

```
\( \text{CO}_2\text{R} \)
```

You will soon start to appreciate what is available as you see which compounds we use as starting materials. Supplier’s catalogues are available free for the asking and make quite useful
textbooks. You could consider getting one. In addition, online and CD catalogues are available in most chemistry departments and can be searched by structure.

**Donor and acceptor synthons**

You’ve now met a variety of synthons and it’s useful to be able to classify them as donor or acceptor synthons. We call a negatively polarized synthon a donor synthon and give it the symbol ‘d’. Positively polarized synthons are called acceptor synthons and are given the symbol ‘a’.

We can classify the synthons further according to where the functional group is in relation to the reactive site. The first synthon in the diagram below, which corresponds to an aldehyde, we call an a₁ synthon because it is an acceptor that carries a functional group on the same carbon as its reactive centre. The second is a d² synthon because it is a donor whose reacting site is in the 2-position relative to the carbonyl group. Earlier you met two other types of synthon, corresponding to epoxide and Michael acceptor, and we can now classify these as a² and a³ synthons.

This terminology is useful because it reduces synthons to the bare essentials: what polarity they are and where the polarity is sited. The actual functional group they carry is, as you now appreciate, less important because FGI will usually allow us to turn one functional group into another.

**Synthons are classified as a (acceptor) or d (donor)**

A number shows the position of the acceptor or donor site relative to a functional group.

An example of an a₁ synthon is a carbonyl compound and an example of a d² synthon is an enolate or an enolate equivalent.

**Two-group C–C disconnections**

**1,3-Difunctionalized compounds**

It’s not only Grignard reagents that will react with aldehydes or ketones to make alcohols: enolates will too—we spent Chapter 26 discussing this reaction, the aldol reaction, its variants, and ways to control it.

The aldol reaction is extremely important in organic synthesis because it makes compounds with two functional groups in a 1,3-relationship. Whenever you spot this 1,3-relationship in a target molecule—think aldol! In disconnection terms we can represent it like this.
We call this disconnection a two-group C–C disconnection because we are using the OH and the C=O groups together to guide our disconnection. The disconnection gives us a d^2 synthon, for which we shall use an enolate equivalent, and an a' synthon, for which we shall use an aldehyde or a ketone. Chapter 26 has many examples and perhaps gingerol is the best. As soon as you see the 1,3-relationship, the disconnection should be obvious.

The β-hydroxy carbonyl products of aldol reactions are often very easily dehydrated to give α,β-unsaturated carbonyl compounds and if you spot an α,β-unsaturated carbonyl group in the molecule, you should aim to make it by an aldol reaction. You will first need to do an FGI to the β-hydroxy carbonyl compound, then disconnect as before.

This aldehyde is an intermediate in the synthesis of the tranquillizer oxanamide. Because both components of the aldol reaction are the same, no special precautions need to be taken to prevent side reactions occurring. In the synthesis, the dehydration happens spontaneously.

Because this disconnection of unsaturated carbonyl compounds is so common, it’s often written using a shorthand expression.

The next compound was needed for an early synthesis of carotene. Again, it’s an α,β-unsaturated ketone so we can disconnect using the same ‘α,β’ disconnection. The aldehyde generated by this first disconnection is also α,β-unsaturated, so we can do another α,β disconnection, back to a ketone whose synthesis we have already discussed (p. 708).

An aldol reaction using the enolate of acetaldehyde and requiring it to react with a ketone is doomed to failure: acetaldehyde itself is far too good an electrophile. In the forward synthesis, therefore, this first step was carried out at the ester oxidation level, and the ester was subsequently converted to the aldehyde by a reduction of the kind discussed in Chapter 23.
There was no problem with selectivity in the second aldol reaction because the aldehyde is not enolizable. The Reformatsky reaction in this sequence illustrates the fact that, as you saw in Chapter 26, aldol-type reactions happen at the ester oxidation level as well, and you should equally look to disconnect β-hydroxy or α,β-unsaturated esters, acids, or nitriles in this way. Just remember to look for 1,3-relations, convert the functional groups to oxygen-based ones, and disconnect them to $d^2$ plus $a^1$ synthons.

The next compound was needed when chemists were developing a thromboxane antagonist to inhibit blood clot formation. You can immediately spot the 1,3-relationship between the ester and the hydroxyl group, so 1,3-diO disconnection is called for.

A good equivalent for the ‘ester enolate’ $d^2$ synthon is a β-dicarbonyl compound because it can easily be disconnected to diethyl malonate and an alkylating agent.

This unsaturated amide is known as cinflumide and is a muscle relaxant. Disconnection of the amide gives an acid chloride that we can make by FGI from the acid. You should then spot the α,β-unsaturated carbonyl disconnection, a masked 1,3-diO disconnection, back to $m$-fluorobenzaldehyde.

Again, the forward reaction was best done using malonate chemistry, but the variant with malonic acid was used (p. 630). The cyclopropylamine unit (here as an amide) is present in many biologically active compounds and the free amine is available.

**Look out for concealed functional group relationships**

The analgesic doxpicomine is a more difficult problem than those you have seen so far. At first sight it has no useful disconnections, especially as there are no carbonyl groups. However,
removal of the acetal reveals a 1,3-diol that could be formed by reduction of a much more promising diester.

**doxpicomine: retrosynthetic analysis I**

![Image of retrosynthetic analysis I](image)

The diester has a 1,3-diCO relationship and could be disconnected but we have in mind using malonate so we would rather disconnect the alternative 3-amino carbonyl compound (the MeN group has a 1,3-relationship with both ester groups) by a 1,3-diX disconnection giving an unsaturated ester. This α,β-unsaturated ester disconnects nicely to a heterocyclic aldehyde and diethyl malonate.

**doxpicomine: retrosynthetic analysis II**

![Image of retrosynthetic analysis II](image)

The synthesis is shorter than the retrosynthetic analysis and involves only four steps. Good retrosynthetic analysis, using two-group disconnections, should lead to short syntheses.

**doxpicomine: synthesis**

![Image of synthesis](image)

**Aldol-style disconnections with N and O in a 1,3-relationship: I**

Nitriles form another important class of compounds that undergoes aldol-type additions to aldehydes and ketones. Because nitriles can be reduced to amines, this reaction provides another useful route to 3-amino alcohols.

![Image of Aldol-style disconnections with N and O in a 1,3-relationship: I](image)

This reaction, coupled with the reduction of cyanohydrins (Chapter 6), means that compounds with either a 1,3- or a 1,2-relationship between N and O can be made from nitriles.

![Image of Aldol-style disconnections with N and O in a 1,3-relationship: II](image)

Venlafaxine is an antidepressant and, like many neuroactive agents, it is an amino-alcohol. In this case, the two functional groups are 1,3-related, so we aim to use a 1,3-diO disconnection. Usually, you would convert the amine to an alcohol to simplify the disconnection, but
by spotting the opportunity for using a nitrile you can avoid the need for this extra step. A preliminary removal of the two N-Me groups is necessary.

In the forward synthesis, it turned out that the nitrile reduction was best done using hydrogen and a metal (Rh) catalyst. The final methylation of the primary amine had to be done via the imine and iminium ion (see Chapter 23) to prevent further unwanted alkylations. The reagent was an excess of formaldehyde (methanal CH₂=O) in the presence of formic acid (HCO₂H), which acts as a reducing agent.

**Aldol-style disconnections with N and O in a 1,3-relationship: II—the Mannich reaction**

Another important reaction for making amines with a 1,3-relationship to a carbonyl group is the Mannich reaction. You met this reaction in Chapter 26 as a way of doing otherwise unreliable aldol additions to formaldehyde. Because the amine is introduced directly and not by reduction of a nitrile, it can have two alkyl groups from the start. Compare this scheme with the one above using a nitrile group as the source of the amine.

Our example is clobutinol—an antitussive (cough medicine). A preliminary 1,1 C–C disconnection of the tertiary alcohol is necessary to provide a 3-amino ketone that we can make by a Mannich reaction. The product is a mixture of diastereoisomers.
You can immediately spot the 1,3 relationship in this analogue of the antidepressant nisoxetine, but, unfortunately, it can’t be disconnected straight back to an amino-alcohol because that would require nucleophilic substitution on an electron-rich aromatic ring. We have to disconnect the ether on the other side, giving an alkyl chloride.

nisoxetine analogue: retrosynthetic analysis

Using Guideline 5 (p. 709) we want to convert the halide to an oxygen-based group, and a sensible solution is to choose the ketone. 1,3-Disconnection of this compound corresponds to a Mannich reaction. This is another case where FGI of the amine to an alcohol is not desirable because the Mannich reaction will produce the amine directly.

nisoxetine analogue: synthesis

The Claisen ester disconnection: a 1,3-diO relationship needing two carbonyl groups

1,3-Diketones can be disconnected in a similar way: this time the disconnection corresponds to a Claisen condensation, but it’s still 1,3-diO and again you need to look out for the 1,3 relationship. The synthons are still d^2 plus a^1 but the a^1 synthon is used at the ester oxidation level. This diketone is the starting material for the synthesis of the antidepressant tazadolene. With 1,3-diketones, there’s always a choice where to disconnect, and you should be guided by which disconnection (a) corresponds to the most reliable reaction and (b) gives the simplest starting materials. In this case, it’s much better to disconnect back to cyclohexanone.

TWO-GROUP C–C DISCONNECTIONS
The 1,3-dicarbonyl relationship may not be revealed in the target molecule and C–hetero-atom disconnections or FGIs may be needed before the 1,3-diO C–C disconnection. Bropirimine is a bromine-containing antiviral and anticancer drug. The bromine atom can be put in last of all by electrophilic bromination.

Disconnection of two C–N bonds removes a molecule of guanidine and reveals a 1,3-dicarbonyl relationship with a straightforward disconnection.

In the event, the 1,3-dicarbonyl was made using malonate chemistry with an unusual twist: the lithium derivative gave C–acylation in good yield. Simply refluxing the product with guanidine formed the heterocycle and bromination gave bropirimine.

**Summary: 1,3-diO disconnections**

3-hydroxy carbonyls and α,β-unsaturated carbonyls: use the aldol reaction

3-amino ketones and alcohols: use Mannich or nitrile aldol

1,3-diketones: use the Claisen condensation
1,5-Related functional groups

This compound has a 1,5 rather than a 1,3 relationship between two carbonyl groups. Disconnection to give an enolate as one reagent therefore requires an $\alpha^3$ rather than an $\alpha^1$ synthon: in other words a Michael acceptor.

As discussed in Chapter 25, the synthesis will be successful only if (a) the right reagent enolizes and (b) the nucleophile undergoes conjugate (and not direct 1,2-) addition to the unsaturated carbonyl compound. Malonate derivatives enolize easily and do Michael additions and are therefore a good choice for this type of reaction.

Michael addition of enolates to $\alpha,\beta$-unsaturated compounds is a good way of making 1,5-difunctionalized compounds, and you should look for these 1,5-relationships in target molecules with a view to making them in this way. Our example is rogletimide, a sedative that can be disconnected to a 1,5-diester. Further 1,5-diCO disconnection gives a compound we made earlier by ethylation of the ester enolate.

The synthesis was most efficient with an unsaturated amide as Michael acceptor.

'Natural reactivity' and 'umpolung'

Cast your mind back over the synthons we have used in these two-group C–C disconnections.
Notice that the acceptor synthons have odd numbers; the donor synthon has an even number: donor and acceptor properties alternate along the chain as we move away from a carbonyl group. This ‘natural reactivity’ of carbonyl compounds explains why we find it easy to discuss ways of making 1,3- and 1,5-difunctionalized compounds—because they arise from a\(^1\) + d\(^2\) and from a\(^2\) + d\(^3\). Reagents corresponding to synthons like d\(^1\) or a\(^2\) are rarer, and therefore compounds with 1,2- or 1,4-related functional groups require special consideration retrosynthetically.

You have in fact met one example of each of the ‘unnatural’ synthons with a\(^2\) and d\(^1\) reactivity. Such synthons are given the German name *umpolung*, meaning ‘inverse polarity’, because their natural reactivity is reversed, and umpolung reagents are the key to the synthesis of 1,2- and 1,4-difunctionalized compounds.

We shall finish this chapter by looking at disconnections of 1,2- and 1,4-difunctionalized compounds because these require us to use reagents with umpolung equivalent to d\(^1\), d\(^3\), a\(^2\), and a\(^4\) synthons. There are very many reagents for these synthons—if you are interested to learn more, consult a specialized book.

### 1,2-Difunctional compounds

You met ways of making 1,2-difunctionalized compounds when we first talked about two-group disconnections, and we used an epoxide as an a\(^2\) synthon. Epoxides are, of course, also 1,2-functionalized, and in fact this is often the key to making 1,2-functionalized compounds: use something with the 1,2 relationship already in place. You saw lots of examples of this type of strategy earlier in this chapter. Perhaps the simplest approach is electrophilic addition to alkenes. If the alkene is made by a Wittig reaction, the disconnection is (eventually) between the two functionalized carbon atoms in the target molecule. This example shows dihydroxylation as the electrophilic addition but there is also epoxidation, bromination, and bromination in water to give Br and OH as the functional groups.

A normal C–C disconnection is also a possibility, but disconnection to the ‘natural’ a\(^1\) synthon and the umpolung d\(^1\) is necessary. One very useful umpolung reagent is cyanide, and you can see it in action in this synthesis of the tranquillizer phenaglycodol. The tertiary alcohol with two R groups the same should prompt you to think of doing a double Grignard addition to an ester. FGI then reveals the nitrile functional group necessary for a 1,2-di\(\mathrm{X}\) disconnection to cyanide plus ketone.

The starting material is obviously available by a Friedel–Crafts acylation of chlorobenzene and the rest of the synthesis follows. Note that the nitrile can be converted directly into the ester with acidic ethanol and that an excess of Grignard reagent is needed because the free OH group destroys some of it.
1,4-Difunctional compounds

There are more possibilities here and we shall finish this chapter with a brief analysis of them to show you how much of this subject lies beyond what we can do in this book.

If we start with a 1,4-dicarbonyl compound we might consider first disconnection of the central bond.

We can use an enolate for one reagent but the other will have to have umpolung. This is not a very difficult kind of umpolung as an α-bromo carbonyl compound will do the job nicely if we select our enol(ate) equivalent carefully. In Chapter 25 we suggested enamines for this job. The synthesis becomes:

If we attempt the disconnection of one of the other bonds, two possibilities are available because the two fragments are different. We can use either a d1 + a3 strategy or an a1 + d3 strategy. In each case we have one natural synthon and one with umpolung.

These strategies are more difficult to realize with the reagents you have met so far but conjugate addition of a cyanide to an unsaturated carbonyl compound would be an example of the d1 + a3 strategy. We have included these to try to convince you that there is no escape from umpolung in the synthesis of a 1,4-dicarbonyl compound. If you were making this keto-ester you would have to consider seriously two of the above three strategies.
There is one way to avoid umpolung and that is to make the disconnection outside the 1,4 relationship. As it happens, we have already seen this strategy in action (p. 568). It involves a Friedel–Crafts acylation of benzene (Chapter 21) with a cyclic anhydride and leads directly to this product by quite a short route. This strategy is available only if there happens to be a starting material available to suit any particular case.

\[
\begin{align*}
\text{CO}_2\text{Et} & \rightarrow \text{FGI} \\
\text{CO}_2\text{H} & \rightarrow \text{Friedel–Crafts}
\end{align*}
\]

**To conclude…**

The best synthetic route to a molecule cannot be predicted with certainty. Retrosynthetic analysis allows you to suggest several different strategies for any given target molecule, and thorough literature searching plus experimentation in the laboratory will allow you to whittle the possibilities down to the most likely to succeed. Thinking like this underpins the design of syntheses of molecules, from the relatively simple molecules forming the next generation of drugs or agrochemicals to the most complex molecules known. Retrosynthetic thinking also reinforces the concept that the combination of electrophile and nucleophile is the basis for the understanding of organic reactions. Synthesis and reactions are two sides of the same coin. From now on we shall use the methods and terminology introduced in this chapter when we think that they will help you to develop your understanding.

**Further reading**

Most of the examples are of medicinal compounds and the data are from the patent literature. We suggest you don’t try to use that but, if you are interested in the original work, look at these papers:

**Check your understanding**

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Aromatic heterocycles 1: reactions

Introduction

Benzene is aromatic because it has six electrons in a cyclic conjugated system. We know it is aromatic because it is exceptionally stable, it has a ring current and hence large chemical shifts in the proton NMR spectrum, and it has special chemistry involving substitution rather than addition with electrophiles. This chapter and the next are about the very large number of other aromatic systems in which one or more atoms in the benzene ring are replaced by heteroatoms such as N, O, and S. There are thousands of these systems with five- and six-membered rings, and we will examine just a few.

Online support. The icon in the margin indicates that accompanying interactive resources are provided online to help your understanding: just type www.chemtube3d.com/clayden/123 into your browser, replacing 123 with the number of the page where you see the icon. For pages linking to more than one resource, type 123-1, 123-2 etc. (replacing 123 with the page number) for access to successive links.
Our subject is aromatic heterocycles and it is important that we treat it seriously because most—probably about two-thirds of—organic compounds belong to this class, and they number among them some of the most significant compounds for human beings. If we think only of drugs we can define the history of medicine by heterocycles. Even in the sixteenth century quinine was used to prevent and treat malaria, although the structure of the drug was not known. The first synthetic drug was antipyrine (1887) for the reduction of fevers. The first effective antibiotic was sulfapyridine (1938). The first multi-million pound drug (1970s) was Tagamet, the anti-ulcer drug, and among the most topical of current drugs is Viagra (1997) for treatment of male impotence.

All these compounds have heterocyclic aromatic rings shown in black. Three have single rings, five- or six-membered, two have five- or six-membered rings fused together. The number of nitrogens in the rings varies from one to four. We will start by looking at the simple six-membered ring with one nitrogen atom: pyridine.

Aromaticity survives when parts of benzene’s ring are replaced by nitrogen atoms

There is no doubt that benzene is aromatic. Now we must ask: how can we insert a heteroatom into the ring and retain aromaticity? What kind of atom is needed? If we want to replace one of the carbon atoms of benzene with a heteroatom, we need an atom that can be trigonal to keep the flat hexagonal ring, and that has a $p$ orbital to keep the six delocalized electrons. Nitrogen fits all of these requirements. This is what happens if we replace a CH group in benzene with a nitrogen atom.

The orbitals in the ring have not changed in position or shape and we still have the six electrons from the three double bonds. One obvious difference is that nitrogen is trivalent and thus there is no NH bond. Instead, a lone pair of electrons occupies the space of the C–H bond in benzene.

In theory then, pyridine is aromatic. But is it in real life? The most important evidence comes from the proton NMR spectrum. The six protons of benzene resonate at 7.27 ppm, some 2 ppm downfield from the alkene region, clear evidence for a ring current (Chapter 13). Pyridine is not as symmetrical as benzene but the three types of proton all resonate in the same region. As we will see, pyridine is also very stable and, by any reasonable assessment, pyridine is aromatic.

We could continue the process of replacing, on paper, more CH groups with nitrogen atoms, and would find three new aromatic heterocycles: pyridazine, pyrimidine, and pyrazine:

There is another way in which we might transform benzene into a heterocycle. Instead of using just one electron from N to replace an electron in the $\pi$ system, we could use nitrogen’s lone pair of electrons to replace two electrons in the $\pi$ system. We can substitute a CH=CH unit in benzene with a nitrogen atom providing that we can use the lone pair in the delocalized system. This means putting it into a $p$ orbital. We still have the four electrons from the
remaining double bonds and, with the two electrons of the lone pair on nitrogen, that makes six in all. The nitrogen atom must still be trigonal with the lone pair in a p orbital so the N–H bond is in the plane of the five-membered ring.

The \(^1\)H NMR spectrum of pyrrole is slightly less convincing as the two types of proton on the ring resonate at higher field (6.5 and 6.2 ppm) than those of benzene or pyridine but they still fall in the aromatic rather than the alkene region. Pyrrole is also more reactive towards electrophiles than benzene or pyridine, but it does the usual aromatic substitution reactions (Friedel–Crafts, nitration, halogenation) rather than addition reactions: pyrrole is also aromatic.

Inventing heterocycles by further replacement of CH groups by nitrogen in pyrrole leads to two compounds, pyrazole and imidazole, after one replacement, to two triazoles after two replacements, and to a single tetrazole after three.

All of these compounds are generally accepted as aromatic too as they broadly have the NMR spectra and reactivities expected for aromatic compounds. As you may expect, introducing heteroatoms into the aromatic ring and, even more, changing the ring size actually affect the chemistry a great deal. We must now return to pyridine and work our way more slowly through the chemistry of these important heterocycles to establish the principles that govern their behaviour.

**More nomenclature**

The ending "-ole" is systematic and refers to a five-membered heterocyclic ring. All the five-membered aromatic heterocycles with nitrogen in the ring are sometimes called 'the azoles'. Oxazole and thiazole are used for the oxygen and sulfur analogues of imidazole.

**Pyridine is a very unreactive aromatic imine**

The nitrogen atom in the pyridine ring is planar and trigonal with the lone pair in the plane of the ring. This makes it an imine. Most of the imines you have met before (in Chapter 11, for example), have been unstable intermediates in carbonyl group reactions, but in pyridine we have a stable imine—stable because of its aromaticity. All imines are more weakly basic than saturated amines and pyridine is a weak base with a \(pK_a\) (for its conjugate acid) of 5.5. This means that the pyridinium ion is about as strong an acid as a carboxylic acid.
Pyridine is a reasonable nucleophile for carbonyl groups and is often used as a nucleophilic catalyst in acylation reactions. Esters are often made in pyridine solution from alcohols and acid chlorides (the full mechanism is on p. 199 of Chapter 10).

Pyridine is nucleophilic at the nitrogen atom because the lone pair of electrons on nitrogen cannot be delocalized around the ring. They are in an sp² orbital orthogonal to the p orbitals in the ring and there is no interaction between orthogonal orbitals. Try it for yourself, drawing arrows. All attempts to delocalize the electrons lead to impossible results!

Our main question about the reactivity of pyridine must be this: what does the nitrogen atom do to the rest of the ring? The important orbitals—the p orbitals of the aromatic system—are superficially the same as in benzene, but the more electronegative nitrogen atom will lower the energy of all the orbitals. Lower-energy filled orbitals mean a less reactive nucleophile but a lower-energy LUMO means a more reactive electrophile. This is a good guide to the chemistry
of pyridine. It is less reactive than benzene in electrophilic aromatic substitution reactions, but nucleophilic substitution, which is difficult for benzene, comes easily to pyridine.

**Pyridine is bad at electrophilic aromatic substitution**

The lower energy of the orbitals of pyridine’s π system means that electrophilic attack on the ring is difficult. Another way to look at this is to see that the nitrogen atom destabilizes the cationic would-be intermediate, especially when it can be delocalized onto nitrogen.

An equally serious problem is that the nitrogen lone pair is basic and a reasonably good nucleophile—this is the basis for its role as a nucleophilic catalyst in acylations. The normal reagents for electrophilic substitution reactions, such as nitration, are acidic. Treatment of pyridine with the usual mixture of HNO₃ and H₂SO₄ merely protonates the nitrogen atom. Pyridine itself is not very reactive towards electrophiles: the pyridinium ion is totally unreactive.

Other reactions, such as Friedel–Crafts acylations, require Lewis acids and these too react at nitrogen. Pyridine is a good ligand for metals such as Al(III) or Sn(IV) and, once again, the complex with its cationic nitrogen is completely unreactive towards electrophiles.

**Pyridine does not undergo electrophilic substitution**

Aromatic electrophilic substitution on pyridine is not a useful reaction. The ring is unreactive and the electrophilic reagents attack nitrogen, making the ring even less reactive. Avoid nitration, sulfonation, halogenation, and Friedel–Crafts reactions on simple pyridines.

**Nucleophilic substitution is easy with pyridines**

By contrast, the nitrogen atom makes pyridines more reactive towards nucleophilic substitution, particularly at the 2- and 4-positions, by lowering the LUMO energy of the π system of pyridine. You can see this effect in action in the ease of replacement of halogens in these positions by nucleophiles.
The intermediate anion is stabilized by electronegative nitrogen and by delocalization round the ring. These reactions have some similarity to nucleophilic aromatic substitution (Chapter 22) but are more similar to carbonyl reactions. The intermediate anion is a tetrahedral intermediate that loses the best leaving group to regenerate the stable aromatic system. Nucleophiles such as amines or thiolate anions work well in these reactions.

The leaving group does not have to be as good as chloride in these reactions. Continuing the analogy with carbonyl reactions, 2- and 4-chloropyridines are rather like acid chlorides but we need only use less reactive pyridyl ethers, which react like esters, to make amides. Substitution of a 2-methoxypyridine allows the synthesis of flupirtine.

Pyridones are good substrates for nucleophilic substitution

The starting materials for these nucleophilic substitutions (2- and 4-chloro- or methoxypyridines) are themselves made by nucleophilic substitution on pyridones. If you were asked to propose how 2-methoxypyridine might be made, you would probably suggest, by analogy with the corresponding benzene compound, alkylation of a phenol. Let us look at this in detail.

The starting material for this reaction is a 2-hydroxypyridine that can tautomerize to an amide-like structure known as a pyridone by the shift of the acidic proton from oxygen to nitrogen. In the phenol series there is no doubt about which structure will be stable as the ketone is not aromatic; for the pyridine both structures are aromatic.
In fact, 2-hydroxypyridine prefers to exist as the ‘amide’ because that has the advantage of a strong C=O bond and is still aromatic. There are two electrons in each of the C=C double bonds and two also in the lone pair of electrons on the trigonal nitrogen atom of the amide. Delocalization of the lone pair in typical amide style makes the point clearer.

Pyridones are easy to prepare (see Chapter 30) and can be alkylated on oxygen as predicted by their structure. A more important reaction is the direct conversion to chloropyridines with PCl₃. The reaction starts by attack of the oxygen atom at phosphorus to create a leaving group, followed by aromatic nucleophilic substitution. The overall effect is very similar to acyl chloride formation from a carboxylic acid (Chapter 10).

The same reaction occurs with 4-pyridone, which is also delocalized in the same way and exists in the ‘amide’ form, but not with 3-hydroxypyridine, which exists in the ‘phenol’ form. Its only tautomer is a zwitterion but the pyridine nitrogen is too weak to remove a proton from the hydroxyl group.

Interactive tautomerism between 2-hydroxypyridine and pyridone

Pyridones are easy to prepare (see Chapter 30) and can be alkylated on oxygen as predicted by their structure. A more important reaction is the direct conversion to chloropyridines with PCl₃. The reaction starts by attack of the oxygen atom at phosphorus to create a leaving group, followed by aromatic nucleophilic substitution. The overall effect is very similar to acyl chloride formation from a carboxylic acid (Chapter 10).

The same reaction occurs with 4-pyridone, which is also delocalized in the same way and exists in the ‘amide’ form, but not with 3-hydroxypyridine, which exists in the ‘phenol’ form. Its only tautomer is a zwitterion but the pyridine nitrogen is too weak to remove a proton from the hydroxyl group.

Activated pyridines will do electrophilic aromatic substitution

Useful electrophilic substitutions occur only on pyridines having electron-donating substituents such as NH₂ or OMe. These activate benzene rings too (Chapter 21) but here their help is vital. They supply a non-bonding pair of electrons that raises the energy of the HOMO and carries out the reaction. Simple amino- or methoxypyridines react reasonably well ortho and para to the activating group. These reactions happen in spite of the molecule being a pyridine, not because of it.

A practical example occurs in the manufacture of the analgesic flupirtine where a doubly activated pyridine having both MeO and NH₂ groups is nitrated just as if it were a benzene ring. The nitro group goes in ortho to the amino group and para to the methoxy group. The activation is evidently enough to compensate for the molecule being almost entirely protonated under the conditions of the reaction.

Interactive tautomerism between 2-hydroxypyridine and pyridone

This is the starting material for the flupirtine synthesis on p. 728.
Pyridine N-oxides are reactive towards both electrophilic and nucleophilic substitution

This is all very well if the molecule has such activating groups, but supposing it doesn’t? How are we to nitrate pyridine itself? The answer involves an ingenious trick. We need to activate the ring with an electron-rich substituent that can later be removed and we also need to stop the nitrogen atom reacting with the electrophile. All of this can be done with a single atom!

Because the nitrogen atom is nucleophilic, pyridine can be oxidized to pyridine N-oxide with reagents such as \( m \)-CPBA or just \( \text{H}_2\text{O}_2 \) in acetic acid. These N-oxides are stable dipolar species with the electrons on oxygen delocalized around the pyridine ring, raising the HOMO of the molecule. Reaction with electrophiles occurs at the 2- (ortho) and 4- (para) positions, chiefly at the 4-position to keep away from positively charged nitrogen.

Now the oxide must be removed and this is best done with trivalent phosphorus compounds such as \( (\text{MeO})_3\text{P} \) or \( \text{PCl}_3 \). The phosphorus atom detaches the oxygen atom in a single step to form the very stable \( \text{P} = \text{O} \) double bond. In this reaction the phosphorus atom is acting as both a nucleophile and an electrophile, but mainly as an electrophile since \( \text{PCl}_3 \) is more reactive here than \( (\text{MeO})_3\text{P} \).

The same activation that allowed simple electrophilic substitution—oxidation to the N-oxide—can also allow a useful nucleophilic substitution. The positive nitrogen atom encourages nucleophilic attack and the oxygen atom can be turned into a leaving group with \( \text{PCl}_3 \). Our example is nicotinic acid, whose biological importance we will discuss in Chapter 42.

The N-oxide reacts with \( \text{PCl}_3 \) through oxygen and the chloride ion released in this reaction adds to the most electrophilic position between the two electron-withdrawing groups. Now a simple elimination restores aromaticity and gives a product looking as though it results from chlorination rather than nucleophilic attack.

The reagent \( \text{PCl}_3 \) also converts the carboxylic acid to the acyl chloride, which is hydrolysed back again in the last step. This is a useful sequence because the chlorine atom has been introduced into the 2-position, from which it may in turn be displaced by, for example, amines.
Pyridine N-oxides

Pyridine N-oxides are useful for both electrophilic and nucleophilic substitutions on the same carbon atoms (2-, 4-, and 6-) in the ring.

Nucleophilic addition at an even more distant site is possible on reaction with acid anhydrides if there is an alkyl group in the 2-position. Acylation occurs on oxygen as in the last reaction but then a proton is lost from the side chain to give an uncharged intermediate.

\[ \text{Ac} \rightarrow \text{O} \rightarrow \text{N} \rightarrow \text{O} \]

This compound rearranges with migration of the acetate group to the side chain and the restoration of aromaticity. This may be an ionic reaction or a type of rearrangement that you will learn to call a [3,3]-sigmatropic rearrangement (Chapter 35).

\[ \text{[3,3]-sigmatropic rearrangement} \]

Pyridine as a catalyst and reagent

Since pyridine is abundant and cheap and has an extremely rich chemistry, it is not surprising that it has many applications. One of the simplest ways to brominate benzenes is not to bother with the Lewis acid catalysts recommended in Chapter 21 but just to add liquid bromine to the aromatic compound in the presence of a small amount of pyridine. Only about one mole per cent is needed and even then the reaction has to be cooled to stop it getting out of hand.

As we have seen, pyridine attacks electrophiles through its nitrogen atom. This produces the reactive species, the N-bromo-pyridinium ion, which is attacked by the benzene. Pyridine is a better nucleophile than benzene and a better leaving group than bromide. This is another example of nucleophilic catalysis.

\[ \text{Pyridine recycled} \]

Another way to use pyridine in brominations is to make a stable crystalline compound to replace the dangerous liquid bromine. This compound, known by names such as pyridinium tribromide, is simply a salt of pyridine with the anion Br\(_3\)\(^-\). It can be used to brominate reactive compounds such as alkenes (Chapter 19).

\[ \text{pyridinium tribromide} \]

Both of these methods depend on the lack of reactivity of pyridine’s π system towards electrophiles such as bromine. Notice that, in the first case, both benzene and pyridine are present together. The pyridine attacks bromine only through nitrogen (and reversibly at that) and never through carbon.

Oxidation of alcohols is normally carried out with Cr(VI) reagents (Chapter 23) but these, like the Jones’ reagent (Na\(_2\)Cr\(_2\)O\(_7\) in sulfuric acid), are usually acidic. Some pyridine complexes
of Cr(VI) compounds solve this problem by having the pyridinium ion \((pK_a 5)\) as the only acid. The two most famous are PDC (pyridinium dichromate) and PCC (pyridinium chlorochromate). Pyridine forms a complex with \(\text{CrO}_3\) but this is liable to burst into flames. Treatment with \(\text{HCl}\) gives PCC, which is much less dangerous. PCC is particularly useful in the oxidation of primary alcohols to aldehydes as over-oxidation is avoided in the only slightly acidic conditions (Chapter 23).

\[
\begin{align*}
\text{CrO}_3 + \text{PDC} & \rightarrow \text{PCC} + \text{HCl} \\
\text{PCC} & \rightarrow \text{aldehyde}
\end{align*}
\]

**Bipyridyl (bipy)**

The ability of pyridine to form metal complexes is greatly enhanced in a dimer—the famous ligand ‘bipy’ or \(2,2'\)-bipyridyl. It is bidentate and because of its ‘bite’ it is a good ligand for many transition metals, with a partiality for Fe(II).

\[
\begin{align*}
\text{bipy} & \rightarrow \text{FeCl}_2 \\
\text{FeCl}_2 & \rightarrow \text{bipy}
\end{align*}
\]

It looks like a rather difficult job to persuade two pyridine rings to join together in this way to form bipy. It is indeed very difficult unless you make things easier by using a reagent that favours the product. And what better than Fe(II) to do the job? Bipy is manufactured by treating pyridine with \(\text{FeCl}_2 \cdot 4\text{H}_2\text{O}\) at high temperatures and high pressures. Only a small proportion of the pyridine is converted to the Fe(II) complex of bipy (about 5%) but the remaining pyridine goes back in the next reaction. This is probably a radical process (Chapter 37) within the coordination sphere of Fe(II).

**Six-membered aromatic heterocycles can have oxygen in the ring**

Although pyridine is overwhelmingly the most important of the six-membered aromatic heterocycles, there are oxygen heterocycles, pyrones, that resemble the pyridones. The pyrones are aromatic, although \(\alpha\)-pyrone is rather unstable.

\[
\begin{align*}
\text{2-pyrone or } \alpha\text{-pyrone} & \rightarrow \text{2-pyrone or } \alpha\text{-pyrone} \\
\text{4-pyrone or } \gamma\text{-pyrone} & \rightarrow \text{4-pyrone or } \gamma\text{-pyrone}
\end{align*}
\]

The pyrylium salts are stable aromatic cations and are responsible as metal complexes for some flower colours. Heterocycles with six-membered rings based on other elements (for example, P) do exist but they are outside the scope of this book.
Five-membered aromatic heterocycles are good at electrophilic substitution

Just about everything is the other way round with pyrrole. Electrophilic substitution is much easier than it is with benzene—almost too easy in fact—while nucleophilic substitution is more difficult. Pyrrole is not a base nor can it be converted to an N-oxide. We need to find out why this is. The big difference is that the nitrogen lone pair is delocalized round the ring. The NMR spectrum suggests that all the positions in the ring are about equally electron-rich with chemical shifts about 1 ppm smaller than those of benzene. The ring is flat and the bond lengths are very similar, although the bond opposite the nitrogen atom is a bit longer than the others.

The delocalization of the lone pair can be drawn equally well to any ring atom because of the five-membered ring and we shall soon see the consequences of this. All the delocalization pushes electrons from the nitrogen atom into the ring and we expect the ring to be electron-rich at the expense of the nitrogen atom. The HOMO should go up in energy and the ring become more nucleophilic.

An obvious consequence of this delocalization is the decreased basicity of the nitrogen atom and the increased acidity of the NH group. In fact, the pKₐ of pyrrole acting as a base is about –4, and protonation occurs at carbon below pH –4. By contrast, the NH proton (pKₐ 16.5) can be removed by much weaker bases than those that can remove protons on normal secondary amines. The nucleophilic nature of the ring means that pyrrole is attacked readily by electrophiles. Reaction with bromine requires no Lewis acid and leads to substitution (confirming the aromaticity of pyrrole) at all four free positions. Contrast pyridine’s reactivity with bromine (p. 731): it reacts just once, at nitrogen.

This is a fine reaction in its way, but we don’t usually want four bromine atoms in a molecule so one problem with pyrrole is to control the reaction to give only monosubstitution. Another problem is that strong acids cannot be used. Although protonation does not occur at nitrogen, it does occur at carbon and the protonated pyrrole then adds another molecule like this.

Some reactions can be controlled to give good yields of monosubstituted products. One is the Vilsmeier reaction, in which a combination of an N,N-dimethylamide and POCl₃ is used to make a carbon electrophile in the absence of strong acid or Lewis acid. It is a substitute for the Friedel–Crafts acylation, and works with aromatic compounds at the more reactive end of the scale (where pyrrole is).
In the first step, the amide reacts with POCl₃, which makes off with the amide oxygen atom and replaces it with chlorine. This process would be very unfavourable but for the formation of the strong P–O bond, and is the direct analogy of the chloropyridine-forming reaction you have just seen.

The product from this first step is an iminium cation that reacts with pyrrole to give a more stable iminium salt. The extra stability comes from the conjugation between the pyrrole nitrogen and the iminium group. The work-up with aqueous Na₂CO₃ hydrolyses the imine salt and removes any acid formed. This method is particularly useful because it works well with Me₂NCHO (DMF) to add a formyl (CHO) group. This is difficult to do with a conventional Friedel–Crafts reaction.

You may have noticed that the reaction occurred only at the 2-position on pyrrole. Although all positions react with reagents like bromine, most reagents go for the 2- (or 5-) position and attack the 3- (or 4-) position only if the 2- and 5-positions are blocked. A good example is the Mannich reaction. In these two examples N-methylpyrrole reacts cleanly at the 2-position while the other pyrrole with both 2- and 5-positions blocked by methyl groups reacts cleanly at the 3-position. These reactions are used in the manufacture of the non-steroidal anti-inflammatory compounds tolmecin and clopirac.

Now we need an explanation. The mechanisms for both 2- and 3-substitutions look good and we will draw both, using a generalized E⁺ as the electrophile. Both mechanisms can occur very readily. Reaction in the 2-position is somewhat better than in the 3-position but the difference is small. Substitution is favoured at all positions. Calculations show that the HOMO of pyrrole does indeed have a larger coefficient in the 2-position, and one way to explain this result is to look at the structure of the intermediates. The intermediate from attack at the
2-position has a linear conjugated system. In both intermediates the two double bonds are, of course, conjugated with each other, but only in the first intermediate are both double bonds conjugated with N⁺. The second intermediate is 'cross-conjugated', while the first has a more stable linear conjugated system.

Since electrophilic substitution on pyrroles occurs so easily, it can be useful to block substitution with a removable substituent. This is usually done with an ester group. Hydrolysis of the ester (this is particularly easy with t-butyl esters—see Chapter 23) releases the carboxylic acid, which decarboxylates on heating. There is no doubt that the final electrophilic substitution must occur at C2.

The decarboxylation is a general reaction of pyrroles: it’s a kind of reverse Friedel–Crafts reaction in which the electrophile is a proton (provided by the carboxylic acid itself) and the leaving group is carbon dioxide. The protonation may occur anywhere but it leads to reaction only if it occurs where there is a CO₂H group.

**Furan and thiophene are oxygen and sulfur analogues of pyrrole**

The other simple five-membered heterocycles are furan, with an oxygen atom instead of nitrogen, and thiophene, with a sulfur atom. They also undergo electrophilic aromatic substitution very readily, although not so readily as pyrrole. Nitrogen is the most powerful electron donor of the three, oxygen the next, and sulfur the least. Thiophene is very similar to benzene in reactivity.

Thiophene is the least reactive of the three because the p orbital of the lone pair of electrons on sulfur that conjugates with the ring is a 3p orbital rather than the 2p orbital of N or O, so overlap with the 2p orbitals on carbon is less good. Both furan and thiophene undergo more or less normal Friedel–Crafts reactions, although the less reactive anhydrides (here acetic anhydride, Ac₂O) are used instead of acid chlorides, and weaker Lewis acids than AlCl₃ are preferred.

Notice that the regioselectivity is the same as it was with pyrrole—the 2-position is more reactive than the 3-position in both cases. The product ketones are less reactive towards electrophiles than the starting heterocycles and deactivated furans can even be nitrated.
with the reagents used for benzene derivatives. Notice that reaction has occurred at the 5-position in spite of the presence of the ketone. The preference for 2- and 5-substitution is quite marked.

**Electrophilic addition may be preferred to substitution with furan**

So far, thiophenes and furans look much the same as pyrrole but there are other reactions in which they behave quite differently and we shall now concentrate on those. Furan is less aromatic than pyrrole, and if there is the prospect of forming stable bonds such as C–O single bonds by addition, this may be preferred to substitution. A famous example is the reaction of furan with bromine in methanol. In non-hydroxylic solvents, polybromination occurs as expected, but in MeOH no bromine is added at all!

Bromination must start in the usual way, but a molecule of methanol captures the first formed cation in a 1,4-addition to furan.

The bromine atom that was originally added is now pushed out by the furan oxygen atom to make a relatively stable conjugated oxonium ion, which adds a second molecule of methanol.

This product conceals an interesting molecule. At each side of the ring we have an acetal, and if we were to hydrolyse the acetals, we would have ‘maleic dialdehyde’ (cis-butenedial)—a molecule that is too unstable to be isolated. The furan derivative may be used in its place.

The same 1,4-dialdehyde can be made by oxidizing furan with the mild oxidizing agent dimethyldioxirane, which you met on p. 432. In this sequence, it is trapped in a Wittig reaction to give an E,Z-diene, which is easily isomerized to E,E.

We can extend this idea of furan being the origin of 1,4-dicarbonyl compounds if we consider that furan is, in fact, an enol ether on both sides of the ring. If these enol ethers were hydrolysed we would get a 1,4-diketone.
This time the arrow is solid, not dotted, because this reaction really happens. You will discover in the next chapter that furans can also be made from 1,4-diketones so this whole process is reversible. The example we are choosing has other features worth noting. The cheapest starting material containing a furan is furan-2-aldehyde or ‘furfural’, a by-product of breakfast cereal manufacture. Here it reacts in a typical Wittig process with a stabilized ylid.

Now comes the interesting step: treatment of this furan with acidic methanol gives a white crystalline compound having two 1,4-dicarbonyl relationships. You might like to try and draw a mechanism for this reaction.

The thiophene ring can also be opened up, but in a very different way. Reductive removal of the sulfur atom with Raney nickel reduces not only the C–S bonds but also the double bonds in the ring and the four carbons in the ring form a saturated alkyl chain. If the reduction follows two Friedel–Crafts reactions on thiophene the product is a 1,6-diketone instead of the 1,4-diketones from furan. Thiophene is well behaved in Friedel–Crafts acylations, and reaction occurs at the 2- and 5-positions unless these are blocked.

**Lithiation of thiophenes and furans**

A reaction that furans and thiophenes do particularly well and that fits well with these last two reactions is metallation, particularly lithiation, of a C–H group next to the heteroatom. Metallation of benzene rings (Chapter 24) is carried out by lithium–halogen (Br or I) exchange—a method that works well for heterocycles too as we will see later with pyridine—or by directed (ortho) lithiation of a C–H group next to an activating group such as OMe. With thiophene and furan, the heteroatom in the ring provides the necessary activation.

Activation is by coordination of O or S to Li followed by proton removal by the butyl group—the by-product is gaseous butane. These lithium compounds have a carbon–lithium σ bond and are soluble in organic solvents. We shall represent them very simply, but in fact they are typically dimers or more complex aggregates, with the coordination sphere of Li completed by THF molecules.
These lithium compounds are very reactive and will combine with most electrophiles—in this example the organolithium is alkylated by a benzylic halide. Treatment with aqueous acid gives the 1,4-diketone by hydrolysis of the two enol ethers.

\[
\text{O} \quad \text{Ar} \quad \text{Br} \quad \text{O} \quad \text{O}
\]

1. BuLi, Et\(_2\)O  
2. Br\(\text{-}\text{Ar}\)

\[\text{Ar} = \rho\text{-tolyl}\]

\[
\text{H} \quad \text{H} \quad \text{H}_2\text{O}
\]

Treatment of this diketone with \textit{anhydrous} acid would cause recyclization to the same furan (see Chapter 30) but it can alternatively be cyclized in base by an intramolecular aldol reaction (Chapter 26) to give a cyclopentenone.

\[
\text{O} \quad \text{base} \quad \text{O} \quad \text{O}
\]

This completes our exploration of chemistry special to thiophene and furan, and we now return to all three heterocycles (pyrrole in particular) and look at \textit{nucleophilic} substitution.

**More reactions of five-membered heterocycles**

**Nucleophilic substitution requires an activating group**

Nucleophilic substitution is a relatively rare reaction with pyrrole, thiophene, or furan and requires an activating group such as nitro, carbonyl, or sulfonyl, just as it does with benzene (Chapter 22). This intramolecular example is used to make the painkiller ketorolac.

\[
\text{Ph} \quad \text{O} \quad \text{SO}_2\text{Me} \quad \text{MeO}_2\text{C} \quad \text{CO}_2\text{Me}
\]

NaOEt  
\[
\text{Ph} \quad \text{N} \quad \text{SO}_2\text{Me} \quad \text{MeO}_2\text{C} \quad \text{CO}_2\text{Me}
\]

ketorolac

The nucleophile is a stable enolate and the leaving group is a sulfinate anion. An intermediate must be formed in which the negative charge is delocalized onto the carbonyl group on the ring, just as you saw in the benzene ring examples in Chapter 22. Attack occurs at the 2-position because the leaving group is there and because the negative charge can be delocalized onto the ketone from that position.

**Five-membered heterocycles act as dienes in Diels—Alder reactions**

All of the reactions of pyrrole, furan, and thiophene we have discussed so far have been variations on reactions of benzene. But heterocycles also do reactions totally unlike those of benzene and we are now going to explore two of them.
The first is a reaction you will meet in detail in Chapter 34. It is known as the Diels–Alder reaction, and although it has a number of subtleties we will not discuss here, it has a simple cyclic mechanism in which six electrons (three curly arrows) move around to form a new six-membered ring.

Here is an example with the Boc derivative of pyrrole. The electron-deficient Boc group makes pyrrole less nucleophilic and promotes the Diels–Alder reaction with an alkynyl sulfone. Benzene, and even many other heterocycles, will not do this sort of reaction.

\[
\begin{array}{c}
\text{N} \quad \text{Boc} \\
\text{SO}_2\text{Ar} \\
\text{N} \quad \text{Boc} \\
\text{SO}_2\text{Ar}
\end{array}
\]

The product is a useful intermediate in the synthesis of the analgesic epibatidine. Selective reduction of the non-conjugated double bond is followed by addition of a pyridine nucleophile (a lithium derivative can be prepared from a bromopyridine) to the vinyl sulfone.

\[
\begin{array}{c}
\text{N} \quad \text{Boc} \\
\text{SO}_2\text{Ar} \\
\text{N} \quad \text{Boc} \\
\text{SO}_2\text{Ar}
\end{array}
\]

Furan is particularly good at Diels–Alder reactions but it gives the thermodynamic product, the \textit{exo} adduct, because with this aromatic diene the reaction is reversible.

Aromaticity prevents thiophene taking part in Diels–Alder reactions, but oxidation to the sulfone destroys the aromaticity because both lone pairs become involved in bonds to oxygen. The sulfone is unstable and reacts with itself but will also do Diels–Alder reactions. With an alkyne, loss of SO₂ gives a substituted benzene derivative.

Similar reactions occur with \(\alpha\)-pyrones. These are also rather unstable and barely aromatic and they react with alkynes by Diels–Alder reactions followed by reverse Diels–Alder reactions to give benzene derivatives with the loss of CO₂.
Nitrogen anions can be easily made from pyrrole

Pyrrole is much more acidic than comparable saturated amines. The $pK_a$ of pyrrolidine is about 35, but pyrrole has a $pK_a$ of 16.5, making it some $10^{23}$ times more acidic! Pyrrole is about as acidic as a typical alcohol so bases stronger than alkoxides will convert it to its anion. We should not be too surprised at this as the corresponding hydrocarbon, cyclopentadiene, is also extremely acidic, with a $pK_a$ of 15. The reason is that the anions are aromatic with six delocalized $\pi$ electrons. The effect is much greater for cyclopentadiene because the hydrocarbon is not aromatic and much less for pyrrole because it is already aromatic and has less to gain.

In all of the reactions of pyrrole that we have so far seen, new groups have added to the carbon atoms of the ring. The anion of pyrrole is useful because it reacts at nitrogen. The nitrogen atom has two lone pairs of electrons in the anion: one is delocalized around the ring but the other is localized in an $sp^2$ orbital on nitrogen. This high-energy pair is the new HOMO and this is where the molecule reacts. $N$-acylated derivatives in general can be made in this way. A commonly used base is sodium hydride (NaH) but weaker bases produce enough anion for reaction to occur.

$\text{Anions of pyroles react with electrophiles at the nitrogen atom.}$

This is how the $N$-Boc pyrrole was made for use in the synthesis of epibatidine on p. 739. The base used was the pyridine derivative DMAP, which you met earlier in the chapter (p. 726). Its conjugate acid has a $pK_a$ of 9.7 and so produces small, equilibrating amounts of the anion as well as acting as a nucleophilic catalyst. ‘Boc anhydride’ is used as the acylating agent.

Anion formation is important in the next main section of this chapter, which is about what happens when we insert more nitrogen atoms into the pyrrole ring.

Five-membered rings with two or more nitrogen atoms

Imidazole

At the beginning of this chapter we imagined adding more nitrogen atoms to the pyrrole ring and noticed then that there were two compounds with two nitrogen atoms: pyrazole and imidazole.
Only one nitrogen atom in a five-membered ring can contribute two electrons to the aromatic sextet. The other replaces a CH group, has no hydrogen, and is like the nitrogen atom in pyridine. The black nitrogens are the pyrrole-like nitrogens; the green ones are pyridine-like. The lone pairs on the black nitrogens are delocalized round the ring; those on the green nitrogens are localized in sp² orbitals on nitrogen. We can expect these compounds to have properties intermediate between those of pyrrole and pyridine. Imidazole is a stronger base than either pyrrole or pyridine—the imidazolium ion has a \( pK_a \) of almost exactly 7, meaning that it is 50% protonated in neutral water. Imidazole is also more acidic than pyrrole, with a \( pK_a \) of 14.5.

These curious results are a consequence of the 1,3 relationship between the two nitrogen atoms. Both the (protonated) cation and the (deprotonated) anion share the charge equally between the two nitrogen atoms—they are perfectly symmetrical and unusually stable. Another way to look at the basicity of imidazole would be to say that both nitrogen atoms can act at once on the proton being attacked. It has to be the pyridine-like nitrogen that actually captures the proton but the pyrrole nitrogen can help by using its delocalized electrons like this:

Nature makes use of this property by having imidazole groups attached to proteins in the form of the amino acid histidine and using them as nucleophilic, basic, and acidic catalytic groups in enzyme reactions (this will be discussed in Chapter 42). We use this property in the same way when we add a silyl group to an alcohol. Imidazole is a popular catalyst for these reactions.

A weakly basic catalyst is needed here because we want to discriminate between the primary and secondary alcohols in the diol. Imidazole is too weak a base to remove protons from an alcohol (\( pK_a \sim 16 \)) but it can remove a proton after the OH group has attacked the silicon atom.

In fact, the imidazole is also a nucleophilic catalyst of this reaction, and the first step is substitution of Cl by imidazole—that is why the leaving group in the last scheme was shown as ‘X’. The reaction starts off like this:
The same idea leads to the use of carbonyl diimidazole (CDI) as a double electrophile when we want to link two nucleophiles together by a carbonyl group. Phosgene (COCl₂) has been used for this but it is appallingly toxic (it was used in the First World War as a poison gas with dreadful effects). CDI is safer and more controlled. In these reactions imidazole acts (twice) as a leaving group.

\[
\begin{align*}
\text{MeO}_2\text{C} & \quad \text{N\text{Et}} \\
\text{OH} & \quad \overset{\text{CDI}}{\rightarrow} \\
\text{MeO}_2\text{C} & \quad \text{Et} \\
\end{align*}
\]

The amino group probably attacks first to displace one imidazole anion, which returns to deprotonate the ammonium salt. The alcohol can then attack intramolecularly, displacing the second imidazole anion, which deprotonates the OH group in its turn. The other product is just two molecules of imidazole.

The relationship between the delocalized imidazole anion and imidazole itself is rather like that between an enolate anion and an enol. It will come as no surprise therefore that, like an enol, imidazole tautomerizes rapidly at room temperature in solution. For the parent compound the two tautomers are the same, but with unsymmetrical imidazoles the tautomerism is more interesting. We will explore this question alongside electrophilic aromatic substitution of imidazoles. Imidazoles with a substituent between the two nitrogen atoms (position 2) can be nitrated with the usual reagents and the product consists of a mixture of tautomers.

\[
\begin{align*}
\text{H} & \quad \text{N} \\
\text{N} & \quad \overset{\text{R}}{\equiv} \\
\text{N} & \quad \equiv \overset{\text{R}}{\equiv} \\
\text{H} & \quad \\
\end{align*}
\]

The initial nitration may occur at either of the remaining sites on the ring with the electrons coming from the pyrrole-like nitrogen atom. Tautomerism after nitration gives the mixture. Tautomerism is rapid and the tautomers cannot be separated.

The tautomerism can be stopped by alkylation at one of the nitrogen atoms. If this is done in basic solution, the anion is an intermediate and the alkyl group adds to the nitrogen atom next to the nitro group. Again, it does not matter from which tautomer the anion is derived—there is only one anion delocalized over both nitrogen atoms and the nitro group. One reason for the formation of this isomer is that it has the linear conjugated system between the pyrrole-like nitrogen and the nitro group (see p. 734).
Important medicinal compounds are made in this way. The antiparasitic metronidazole comes from 2-methyl imidazole by nitration and alkylation with an epoxide in base.

The triazoles

There are two triazoles, and each has one pyrrole-like nitrogen and two pyridine-like nitrogens. Both triazoles have the possibility of tautomerism (in 1,2,3-triazole the tautomers are identical) and both give rise to a single anion.

The 1,2,4-triazole is more important because it is the basis of the best modern agricultural fungicides as well as drugs for fungal diseases in humans. The extra nitrogen atom, inevitably of the pyridine type, makes it more weakly basic than imidazole, but it increases its acidity so that the anion is now easy to make.

The fungicides are usually made by the addition of the triazole anion to an epoxide or other carbon electrophile. The anion normally reacts at one of the two linked nitrogen atoms (it does not matter which—the product is the same).
A modern example of an agent used against human fungal infections is Pfizer’s fluconazole, which actually contains two triazoles. The first is added as the anion to an α-chloroketone and the second is added to an epoxide made with the sulfur ylid chemistry you met in Chapter 27. Note that weak bases were used to catalyse both of these reactions. Triazole is acidic enough for even NaHCO₃ to produce a small amount of the anion.

![Manufacture of Pfizer’s fluconazole](image)

**Tetrazole**

There is only one isomer of tetrazole or of C-substituted tetrazoles, as there is only one carbon atom in the ring, although there may be several tautomers. The main interest in tetrazoles is that they are rather acidic: the pKₐ for the loss of the NH proton to form an anion is about 5, essentially the same as that of a carboxylic acid. The anion is delocalized over all four nitrogen atoms (as well as the one carbon atom), and four nitrogen atoms do the work of two oxygen atoms.

![Two tautomers of a tetrazole](image)

Because tetrazoles have similar acidities to those of carboxylic acids, they have been used in drugs as replacements for the CO₂H unit when the carboxylic acid has unsatisfactory properties for human medicine. A simple example is the anti-arthritis drug indomethacin whose carboxylic acid group may be replaced by a tetrazole with no loss of activity.

![Indomethacin tetrazole substitute](image)

**Nitrogen atoms and explosions**

Compounds with even two or three nitrogen atoms joined together, such as diazomethane (CH₂N₂) or azides (RN₃), are potentially explosive because they can suddenly give off stable gaseous nitrogen. Compounds with more nitrogen atoms, such as tetrazoles, are likely to be more dangerous and few people have attempted to prepare pentazoles. The limit is reached with diazotetrazole, with the amazing formula CN₆! It is made by diazotization of 5-aminotetrazole, which first gives a diazonium salt.

![Nitrogen atoms and explosions](image)
The diazonium salt is extremely dangerous: ‘It should be emphasised that [the diazonium salt] is extremely explosive and should be handled with great care. We recommend that no more than 0.75 mmol be isolated at one time. Ethereal solutions are somewhat more stable but explosions have occurred after standing at –70 °C for 1 hr.’ So much for that, but what about the diazo compound? It is extremely unstable and decomposes to a carbene with loss of one molecule of nitrogen and then loses two more to give...

\[
\begin{align*}
\text{the diazonium salt} & \quad \text{highly explosive!} \\
\text{the diazo compound} & \quad \text{highly explosive!}
\end{align*}
\]

All that is left is a carbon atom and this is one of very few ways to make carbon atoms chemically. The carbon atoms have remarkable reactions and these have been studied briefly, but the hazardous preparation of the starting materials discourages too much research. However, you will see in the next chapter that 1-amino tetrazole is a useful starting material for making an anti-allergic drug.

Benzo-fused heterocycles

Indoles are benzo-fused pyrroles

Indomethacin and its tetrazole analogue contain pyrrole rings with benzene rings fused to the side. Such bicyclic heterocyclic structures are called indoles and are our next topic. Indole itself has a benzene ring and a pyrrole ring sharing one double bond, or, if you prefer to look at it this way, it is an aromatic system with 10 electrons—eight from four double bonds and the lone pair from the nitrogen atom.

Indole is an important heterocyclic system because it is built into proteins in the form of the amino acid tryptophan (Chapter 42) because it is the basis of important drugs such as indomethacin, and because it provides the skeleton of the indole alkaloids—biologically active compounds from plants including strychnine and LSD (alkaloids are discussed in Chapter 42).

In many ways the chemistry of indole is that of a reactive pyrrole ring with a relatively unreactive benzene ring standing on one side—electrophilic substitution almost always occurs on the pyrrole ring, for example. But indole and pyrrole differ in one important respect. In indole, electrophilic substitution is preferred in the 3-position with almost all reagents whereas it occurs in the 2-position with pyrrole. Halogenation, nitration, sulfonation, Friedel−Crafts acylation, and alkylation all occur cleanly at that position.
This is, of course, the reverse of what happens with pyrrole. Why should this be? A simple explanation is that reaction at the 3-position simply involves the rather isolated enamine system in the five-membered ring and does not disturb the aromaticity of the benzene ring. The positive charge in the intermediate is, of course, delocalized round the benzene ring, but it gets its main stabilization from the nitrogen atom. It is not possible to get reaction in the 2-position without seriously disturbing the aromaticity of the benzene ring.

**Electrophilic substitution on pyrrole and indole**

Pyrrole reacts with electrophiles at all positions but prefers the 2- and 5-positions, while indole much prefers the 3-position.

A simple example of electrophilic substitution is the Vilsmeier formylation with DMF and POCl₃, showing that indole has similar reactivity, if different regioselectivity, to pyrrole. If the 3-position is blocked, reaction occurs at the 2-position and this at first seems to suggest that it is all right after all to take the electrons the ‘wrong way’ round the five-membered ring. This intramolecular Friedel–Crafts alkylation is an example.

An ingenious experiment showed that this cyclization is not as simple as it seems. If the starting material is labelled with tritium (radioactive ³H) next to the ring, the product shows exactly 50% of the label where it is expected and 50% where it is not.

To give this result, the reaction must have a symmetrical intermediate and the obvious candidate arises from attack at the 3-position. The product is formed from the intermediate *spiro* compound, which has the five-membered ring at right angles to the indole ring—each CH₂ group has an exactly equal chance of migrating.

It is now thought that most substitutions in the 2-position go by this migration route but that some go by direct attack with disruption of the benzene ring. A good example of indole’s 3-position preference is the Mannich reaction, which works as well with indole as it does with pyrrole or furan.
The electron-donating power of the indole and pyrrole nitrogens is never better demonstrated than in the use to which these Mannich bases (the products of the reaction) are put. You may remember that normal Mannich bases can be converted to other compounds by alkylation and elimination (see p. 621). No alkylation is needed here as the indole nitrogen can even expel the Me₂N group when NaCN is around as a base and nucleophile. The reaction is slow and the yield not wonderful but it is amazing that it happens at all. The reaction is even easier with pyrrole derivatives.

\text{NaCN} \\
\end{array}
\]

All of the five-membered rings we have looked at have their benzo-derivatives but we will concentrate on just one, 1-hydroxybenzotriazole, both because it is an important compound and because we have said little about simple 1,2,3-triazoles.

**HOBt is an important reagent in peptide synthesis**

1-Hydroxybenzotriazole (HOBt) is a friend in need in the lives of biochemists. It is added to many reactions where an activated ester of one amino acid is combined with the free amino group of another (see Chapter 23 for some examples). It was first made in the nineteenth century by a remarkably simple reaction.

The structure of HOBt appears quite straightforward, except for the unstable N–O single bond, but we can easily draw some other tautomers in which the proton on oxygen—the only one in the heterocyclic ring—can be placed on some of the nitrogen atoms. These structures are all aromatic, the second and third are nitrones, and the third structure looks less good than the other two.

HOBt comes into play when amino acids are being coupled together in the laboratory. The reaction is an amide formation, but in Chapter 23 we mentioned that amino-acyl chlorides cannot be used to make polypeptides—they are too reactive and they lead to side reactions. Instead, activated amino-esters (with good RO⁻ leaving groups) are used, such as the phenyl esters of Chapter 23. It is even more common to form the activated ester in the coupling reaction, using a coupling reagent, the most common being DCC, dicyclohexylcarbodiimide. DCC reacts with carboxylic acids like this:

\[
\begin{array}{c}
\text{N} \\
\text{C} \\
\text{R} \\
\text{R} \\
\end{array}
\]

\[
\begin{array}{c}
\text{BocHN} \\
\text{R} \\
\text{R} \\
\end{array}
\]

\[
\begin{array}{c}
\text{N} \\
\text{C} \\
\text{R} \\
\text{R} \\
\end{array}
\]

\[
\begin{array}{c}
\text{BocHN} \\
\text{R} \\
\text{R} \\
\end{array}
\]

The product ester is activated because substitution with any nucleophile expels this very stable urea as a leaving group.
The problem with attacking this ester directly with the amino group of the second amino acid is that some racemization of the active ester is often found. A better method is to have plenty of HOBt around. It intercepts the activated ester first and the new intermediate does not racemize, mostly because the reaction is highly accelerated by the addition of HOBt. The second amino acid, protected on the carboxyl group, attacks the HOBt ester and gives the dipeptide in a very fast reaction without racemization.

**Putting more nitrogen atoms in a six-membered ring**

At the beginning of the chapter we mentioned the three six-membered aromatic heterocycles with two nitrogen atoms—pyridazine, pyrimidine, and pyrazine. In these compounds both nitrogen atoms must be of the pyridine sort, with lone pair electrons not delocalized round the ring.

We are going to look at these compounds briefly here. Pyrimidine is more important than either of the others because of its involvement in DNA and RNA—you will find this in Chapter 42. All three compounds are very weak bases—hardly basic at all in fact. Pyridazine is slightly more basic than the other two because the two adjacent lone pairs repel each other and make the molecule more nucleophilic (the \( \alpha \) effect again: see p. 513). The chemistry of these very electron-deficient rings mostly concerns nucleophilic attack and displacement of leaving groups such as Cl by nucleophiles such as alcohols and amines. To introduce this subject we need to take one heterocyclic synthesis at this point, although these are properly the subject of the next chapter. The compound maleic hydrazide has been known for some time because it is easily formed when hydrazine is acylated twice by maleic anhydride.

The compound actually prefers to exist as the second tautomer (in the green frame). Reaction with POCl₃, in the way we have seen for pyridine gives the undoubtedly aromatic pyridazine dichloride. Now we come to the point. Each of these chlorides can be displaced in turn with an oxygen or nitrogen nucleophile. Only one chloride is displaced in the first reaction, if that is required, and then the second can be displaced with a different nucleophile.
How is this possible? The mechanism of the reactions is addition to the pyridazine ring followed by loss of the leaving group. When the second nucleophile attacks it is forced to attack a less electrophilic ring. An electron-withdrawing group (Cl) has been replaced by a strongly electron-donating group (NH₂) so the rate-determining step, the addition of the nucleophile, is slower.

The same principle applies to other easily made symmetrical dichloro derivatives of these rings and their benzo analogues. The nitrogen atoms can be related 1,2, 1,3, or 1,4, as in these examples. The first two are used to link the quinine-derived ligands required for the Sharpless asymmetric dihydroxylation, which will be described in Chapter 41.

**Fusing rings to pyridines: quinolines and isoquinolines**

A benzene ring can be fused on to the pyridine ring in two ways, giving the important heterocycles quinoline, with the nitrogen atom next to the benzene ring, and isoquinoline, with the nitrogen atom in the other possible position. Quinoline forms part of quinine (structure at the head of this chapter) and isoquinoline forms the central skeleton of the isoquinoline alkaloids, which we will discuss in Chapter 42. In this chapter we need not say much about quinoline because it behaves rather as you would expect—its chemistry is a mixture of that of benzene and pyridine. Electrophilic substitution favours the benzene ring and nucleophilic substitution favours the pyridine ring. So nitration of quinoline gives two products—the 5-nitroquinolines and the 8-nitroquinolines—in about equal quantities (although you will realize that the reaction really occurs on protonated quinoline).

This is obviously rather unsatisfactory but nitration is actually one of the better behaved reactions. Chlorination gives ten products (at least!), of which no fewer than five are chlorinated quinolines of various structures. The nitration of isoquinoline is rather better behaved, giving 72% of one isomer (5-nitroisoquinoline) at 0 °C.

To get reaction on the pyridine ring, the N-oxide can be used—as with pyridine itself. A good example is acridine, with two benzene rings, which gives four nitration products, all on the benzene rings. Its N-oxide, on the other hand, gives just one product in good yield—nitration takes place at the only remaining position on the pyridine ring.
In general, these reactions are not of much use and most substituents are put into quinolines during ring synthesis from simple precursors, as we will explain in the next chapter. There are a couple of quinoline reactions that are unusual and interesting. Vigorous oxidation goes for the more electron-rich ring, the benzene ring, and destroys it leaving pyridine rings with carbonyl groups in the 2- and 3-positions.

A particularly interesting nucleophilic substitution occurs when quinoline N-oxide is treated with acylating agents in the presence of nucleophiles. These two examples show that nucleophilic substitution occurs in the 2-position and you may compare these reactions with those of pyridine N-oxide. The mechanism is similar.

In considering quinolines and indoles with their fused rings we kept the benzene and heterocyclic rings separate. Yet there is a way in which they can be combined more intimately, and that is to have a nitrogen atom at a ring junction.

**A nitrogen atom can be at a ring junction**

It has to be a pyrrole-type nitrogen as it must have three σ bonds, so the lone pair must be in a p orbital. This means that one of the rings must be five-membered and the simplest member of this interesting class is called indolizine—it has pyridine and pyrrole rings fused together along a C–N bond. If you examine this structure you will see that there is definitely a pyrrole ring but that the pyridine ring is not all there. Of course, the lone pair and the π electrons are all delocalized but this system, unlike indole and quinoline, is much better regarded as a ten-electron outer ring than as two six-electron rings joined together. Indolizidine reacts with electrophiles on the five-membered rings by substitution reactions as expected.

**Fused rings with more than one nitrogen**

It is easily possible to continue to insert nitrogen atoms into fused ring systems and some important compounds belong to these groups. The purines are part of DNA and RNA, one example is adenine and another is guanine in the box below, but simple purines play an important part in our lives. Coffee and tea owe their stimulant properties to caffeine, a simple trimethyl purine derivative. It has an imidazole ring fused to a pyrimidine ring and is aromatic in spite of the two carbonyl groups.
Uric acid, gout, and allopurinol

Another purine, uric acid, occurs widely in nature—it is used by birds, and to some extent by humans, as a way to excrete excess nitrogen—but it causes much distress in humans when crystalline uric acid is deposited in joints. We call the pain ‘gout’. The solution is a specific inhibitor of the enzyme producing uric acid and it is no surprise that a compound closely resembling uric acid, allopurinol, is the best.

Two of the carbonyl groups have gone and the imidazole ring has been replaced by a pyrazole ring. Purines from DNA are degraded in the body to xanthine, which is oxidized to uric acid. Allopurinol binds to the enzyme xanthine oxidase but inactivates it by not reacting. In fact it imitates not uric acid but the true substrate xanthine in a competitive fashion. This enzyme plays a minor part in human metabolism so inhibiting it is not serious—it just prevents overproduction of uric acid.

Other fused heterocycles have very attractive flavour and odour properties. Pyrazines, in general, are important in many strong food flavours: a fused pyrazine with a ring junction nitrogen atom is one of the most important components in the smell of roast meat. You can read about the simple pyrazine that provides green peppers with their flavour in the box on the next page.

Finally, the compounds in the margin form a medicinally important group of molecules, which includes antitumour compounds for humans and anthelmintics (compounds that get rid of parasitic worms) for animals. They are derived from a 6/5 fused aromatic ring system that resembles the ten-electron system of the indolizine ring system but has three nitrogen atoms.

All this multiple heteroatom insertion is possible only with nitrogen and we need to look briefly at what happens when we combine nitrogen with oxygen or in heterocycles.

Aromatic heterocycles can have many nitrogens but only one sulfur or oxygen in any ring

A neutral oxygen or sulfur atom can have only two bonds and so it can never be like the nitrogen atom in pyridine—it can only be like the nitrogen atom in pyrrole. We can put as many pyridine-like nitrogens as we like in an aromatic ring, but never more than one pyrrole-like nitrogen. Similarly, we can put only one oxygen or sulfur atom in an aromatic ring. The simplest examples are oxazoles and thiazoles, and their less stable isomers isoxazoles and isothiazoles.

The instability of the ‘iso-’ compounds comes from the weak O–N or S–N bond. These bonds can be cleaved by reducing agents, which then usually reduce the remaining functional groups further. The first product from reduction of the N–O bond is an unstable imino-enol. The enol tautomerizes to the ketone and the imine may be reduced further to the amine.

Such heterocycles with even more nitrogen atoms exist but are relatively unimportant and we shall mention just one, the 1,2,5-thiadiazole, because it is part of a drug, timolol.
The discovery of the compound responsible for the flavour of green peppers provides us with a chance to review some spectroscopy. This powerful compound was isolated from the oil of the green pepper (*Capsicum annuum* var. *grossum*). The oil makes up about 0.0001% of the mass of the peppers and the main pepper flavour comes from one compound which is 30% of the oil. It had an even molecular ion at 166 and looks like a compound without nitrogen, perhaps C_{11}H_{18}O. But a high-resolution mass spectrum revealed that M⁺ was actually 166.1102, which corresponds almost exactly to C_{9}H_{14}N_{2}O (166.1106).

The IR had no OH, NH, or C=O peaks, and the proton NMR looked like this.

The ‘CH’ feature in the Me₂CH and CH₃CH signals must be the same CH and it must be the signal at 1.1–2.4 ppm described as a ‘multiplet’ as it is the only one showing enough coupling. It will be a septuplet of triplets, that is, 21 lines. We can easily reconstruct the aliphatic part of the molecule because it has two methyl groups and a CH₂ group joined to the same CH group.

We also have an OMe group (only oxygen is electronegative enough to take a methyl group to nearly 4 ppm). This adds up to C_{9}H_{12}O. What is left? Only C_{4}H_{2}N_{2}—and no clue yet as to the nitrogen functionality. We also have an aromatic ring that must have nitrogen in it (because there are only five carbon atoms—not enough for a benzene ring!) and the coupling constant between the two aromatic hydrogens is 2.4 Hz. So could we perhaps have a pyrrole ring? Well, no, and for two reasons. If we try and construct such a molecule, we can’t fit in the last nitrogen! If we put it on the end of the dotted line, it would have to be an NH₂ group, and there isn’t one.

A better reason is that the chemical shifts are all wrong. The protons on an electron-rich pyrrole ring come at around 6–6.5 ppm, upfield from benzene (7.27 ppm). But these protons are at 7.8–8.0 ppm, downfield from benzene. We have a deshielded (electron-poor) ring, not a shielded (electron-rich) ring. From what you now know of heterocyclic chemistry, the ring must be a six-membered one, and we must put both nitrogen atoms in the ring. There are three ways to do this.
The small coupling constant really fits the pyrazine alone and the chemical shifts are about right for that molecule too, although not as far downfield. But we have a MeO group on the ring feeding electrons into the aromatic system and that will increase the shielding slightly and move the protons upfield. This gives us a unique structure.

There is only one way to be sure and that is to make this compound and see if it is the same as the natural product in all respects, including biological activity. The investigators did this but then wished that they hadn’t! The structure was indeed correct but the biological activity—the smell of green peppers—was so intense that they had to seal up the laboratory where the work was done as no one would work there. Human beings can detect 2 parts in $10^{12}$ of this compound in water.

There are thousands more heterocycles out there

But we’re not going to discuss them and we hope you’re grateful. In fact, it’s about time to stop, and we shall leave you with a hint of the complexity that is possible. If pyrrole is combined with benzaldehyde a good yield of a highly coloured crystalline compound is formed: a porphyrin. Now, what about this ring system—is it aromatic? It’s certainly highly delocalized and your answer to the question clearly depends on whether you include the nitrogen electrons or not. In fact, if you ignore the pyrrole-like nitrogen atoms but include the pyridine-like nitrogens and weave round the periphery, you have nine double bonds and hence 18 electrons—a $4n+2$ number. Most people agree that these compounds are aromatic.

Some heterocycles are simple, some very complex, but we cannot live without them. We shall end this chapter with a wonderful story of heterocyclic chemistry at work. Folic acid is much in the news today as a vitamin that is particularly important for pregnant women, but is involved in the metabolism of all living things. Folic acid is built up in nature from three pieces: a heterocyclic starting material (red), $p$-aminobenzoic acid (black), and the amino acid glutamic acid (green). Here you see the precursor, dihydrofolic acid.

Although folic acid is vital for human health, we don’t have the enzymes to make it: it’s a vitamin, which means we must take it in our diet or we die. Bacteria, on the other hand, do make folic acid. This is very useful because it means that if we inhibit the enzymes of folic acid synthesis we can kill bacteria but we cannot possibly harm ourselves as we don’t have those enzymes. The sulfa drugs, such as sulfamethoxypyridazine or sulfamethoxazole, imitate $p$-aminobenzoic acid and inhibit the enzyme dihydropteroate synthase. Each has a new heterocyclic system added to the sulfonamide part of the drug.
The next step in folic acid synthesis is the reduction of dihydrofolate to tetrahydrofolate. This can be done by both humans and bacteria, and although it looks like a rather trivial reaction (see black portion of molecules), it can only be done by the very important enzyme dihydrofolate reductase.

Although both bacteria and humans have this enzyme, the bacterial version is different enough for us to attack it with specific drugs. An example is trimethoprim—yet another heterocyclic compound with a pyrimidine core (black on diagram). These two types of drugs that attack the folic acid metabolism of bacteria are often used together.

We will see in the next chapter how to make these heterocyclic systems and, in Chapter 42, other examples of how important they are in living things.

**Which heterocyclic structures should you learn?**

This is, of course, nearly a matter of personal choice. Every chemist really must know the names of the simplest heterocycles and we give those below along with a menu of suggestions. First of all, those every chemist must know:

1. **Imidazole**
   - The most important five-membered ring with two nitrogen atoms
   - Part of the amino acid histidine, occurs in proteins and is important in enzyme mechanisms
   - A substituted imidazole is an essential part of the anti-ulcer drug cimetidine

   ![Imidazole](imidazole.png)

   ![Histidine](histidine.png)

   ![Cimetidine](cimetidine.png)

2. **Pyrimidine**
   - The most important six-membered ring with two nitrogen atoms
   - Three functionalized pyrimidines are part of DNA and RNA structure, e.g. uracil
   - Many antiviral drugs, particularly anti-HIV drugs, are modified pieces of DNA and contain pyrimidines

   ![Pyrimidine](pyrimidine.png)

   ![Uracil](uracil.png)

   ![AZT](AZT.png)
3 Quinoline

one of two benzo-pyridines with many applications

occurs naturally in the important antimalarial drug quinine

'cyanine' dyestuffs used as sensitizers for particular light wavelengths in colour photography

4 Isoquinoline

the other benzo-pyridine with many applications

occurs naturally in the benzyl isoquinoline alkaloids like papaverine

5 Indole

the more important benzo-pyrrole

occurs in proteins as tryptophan and in the brain as the neurotransmitter serotonin (5-hydroxytryptamine)

Important modern drugs are based on serotonin, including sumatriptan for migraine and ondansetron, an antiemetic for cancer chemotherapy

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at http://www.oxfordtextbooks.co.uk/orc/clayden2e/
In this chapter you will revisit the heterocyclic systems you have just met and find out how to make them. You’ll also meet some new heterocyclic systems and find out how to make those. With so many heterocycles to consider, you’d be forgiven for feeling rather daunted by this prospect, but do not be alarmed. Making heterocycles is easy—that’s precisely why there are so many of them. Just reflect…

- Intramolecular reactions are preferred to intermolecular reactions.
- Forming five- and six-membered rings is easy.
- We are talking about aromatic, that is, very stable molecules.

If we are to use these bullet points to our advantage we must think strategy before we start. When we were making benzene compounds we usually started with a preformed simple benzene derivative—toluene, phenol, aniline—and added side chains by electrophilic substitution. In this chapter our strategy will usually be to build the heterocyclic ring with most of its substituents already in place and add just a few others, perhaps by electrophilic substitution, but mostly by nucleophilic substitution.

We will usually make the rings by cyclization reactions with the heteroatom (O, N, S) as a nucleophile and a suitably functionalized carbon atom as the electrophile. This electrophile
will almost always be a carbonyl compound of some sort and this chapter will help you revise your carbonyl chemistry from Chapters 10, 11, 20, 25, and 26 as well as the approach to synthesis described in Chapter 28.

**Thermodynamics is on our side**

Some of the syntheses we will meet will be quite surprisingly simple! It sometimes seems that we can just mix a few things together with about the right number of atoms and let thermodynamics do the rest. A commercial synthesis of pyridines combines acetaldehyde and ammonia under pressure to give a simple pyridine.

The yield is only about 50%, but what does that matter in such a simple process? By counting atoms we can guess that four molecules of aldehyde and one of ammonia react, but exactly how is a triumph of thermodynamics over mechanism. Much more complex molecules can sometimes be made very easily too. Take allopurinol, for example, which you met in the last chapter. It is not too difficult to work out where the atoms go—the hydrazine obviously gives rise to the pair of adjacent nitrogen atoms in the pyrazole ring and the ester group must be the origin of the carbonyl group (the colours and numbers illustrate this)—but would you have planned this synthesis?

We will see that this sort of ‘witch’s brew’ approach to heterocyclic synthesis is restricted to a few basic ring systems and that, in general, careful planning is just as important here as elsewhere. The difference is that the synthesis of aromatic heterocycles is very forgiving—it often ‘goes right’ instead of going wrong. We’ll now look seriously at planning the synthesis of aromatic heterocycles.

**Disconnect the carbon–heteroatom bonds first**

The simplest synthesis for a heterocycle emerges when we remove the heteroatom and see what electrophile we need. We shall use pyrroles as examples. The nitrogen forms an enamine on each side of the ring and we know that enamines are made from carbonyl compounds and amines.

If we do the same disconnection with a pyrrole, omitting the intermediate stage, we can repeat the C–N disconnection on the other side too:

What we need is an amine—ammonia in this case—and a diketone. If the two carbonyl groups have a 1,4 relationship we will get a pyrrole out of this reaction. So hexane-2,5-dione reacts with ammonia to give a high yield of 2,5-dimethyl pyrrole. Making furans is even easier because the heteroatom (oxygen) is already there. All we have to do is to dehydrate the 1,4-diketone instead of making enamines from it. Heating with acid is enough.
Avoiding the aldol product

1,4-Diketones also self-condense rather easily in an intramolecular aldol reaction (see Chapter 26, p. 636) to give a cyclopentenone with an all-carbon five-membered ring. This too is a useful reaction but we need to know how to control it. The usual rule is:

- Base gives the cyclopentenone.
- Acid gives the furan.

For thiophenes we could in theory use H₂S or some other sulfur nucleophile but, in practice, an electrophilic reagent is usually used to convert the two C=O bonds to C=S bonds. Thioketones are much less stable than ketones and cyclization is swift. Reagents such as P₂S₅ or Lawesson’s reagent are the usual choice here.

● Making five-membered heterocycles

Cyclization of 1,4-dicarbonyl compounds with nitrogen, sulfur, or oxygen nucleophiles gives the five-membered aromatic heterocycles pyrrole, thiophene, and furan.

It seems a logical extension to use a 1,5-diketone to make substituted pyridines but there is a slight problem here as we will introduce only two of the required three double bonds when the two enamines are formed. To get the pyridine by enamine formation we should need a double bond somewhere in the chain between the two carbonyl groups. But here another difficulty arises—it will have to be a cis (Z) double bond or cyclization would be impossible.

On the whole it is easier to use the saturated 1,5-diketone and oxidize the product to the pyridine. As we are going from a non-aromatic to an aromatic compound, oxidation is easy and we can replace the question mark above with almost any simple oxidizing agent, as we shall soon see.

● Making six-membered heterocycles

Cyclization of 1,5-dicarbonyl compounds with nitrogen nucleophiles leads to the six-membered aromatic heterocycle pyridine.

Heterocycles with two nitrogen atoms come from the same strategy

Reacting a 1,4-diketone with hydrazine (NH₂NH₂) makes a double enamine again and this is only an oxidation step away from a pyridazine. This is also a good synthesis.
If we use a 1,3-diketone instead we will get a five-membered heterocycle and the imine and enamine formed are enough to give aromaticity without any need for oxidation. The product is a pyrazole. The two heteroatoms do not, of course, need to be joined together for this strategy to work. If an amidine is combined with the same 1,3-diketone we get a six-membered heterocycle. As the nucleophile contains one double bond already, an aromatic pyrimidine is formed directly.

Since diketones and other dicarbonyl compounds are easily made by enolate chemistry (Chapters 25, 26, and 28) this strategy has been very popular and we will look at some detailed examples before moving on to more specialized reactions for the different classes of aromatic heterocycles.

**Pyrroles, thiophenes, and furans from 1,4-dicarbonyl compounds**

We need to make the point that pyrrole synthesis can be done with primary amines as well as with ammonia and a good example is the pyrrole needed for clopirac, a drug we discussed in Chapter 29. The synthesis is very easy.

For an example of furan synthesis we choose menthofuran, which contributes to the flavour of mint. It has a second ring, but that is no problem if we simply disconnect the enol ethers as we have been doing so far.

The starting material is again a 1,4-dicarbonyl compound but as there was no substituent at C1 of the furan, that atom is an aldehyde rather than a ketone. This might lead to problems in the synthesis so a few changes (using the notation you met in Chapter 28) are made to the intermediate before further disconnection.

- Halo aldehydes are unstable and should be avoided.
Notice in particular that we have ‘oxidized’ the aldehyde to an ester to make it more stable—in the synthesis reduction will be needed. Here is the alkylation step of the synthesis, which does indeed go very well with the α-iodo-ester.

Cyclization with acid now causes a lot to happen. The 1,4-dicarbonyl compound cyclizes to a lactone, not to a furan, and the redundant ester group is lost by hydrolysis and decarboxylation. Notice that the double bond moves into conjugation with the lactone carbonyl group. Finally, the reduction gives the furan. No special precautions are necessary—as soon as the ester is partly reduced, it loses water to give the furan whose aromaticity prevents further reduction even with LiAlH₄.

A reminder

Cyclization of 1,4-dicarbonyl compounds with nitrogen, sulfur, or oxygen nucleophiles gives the five-membered aromatic heterocycles pyrrole, thiophene, and furan.

Now we need to take these ideas further and discuss an important pyrrole synthesis that follows this strategy but includes a cunning twist. It all starts with the porphyrin found in blood. In Chapter 29 we gave the structure of porphyrin and showed that it contains four pyrrole rings joined in a macrocycle. We are going to look at one of those pyrroles.

Porphyrins can be made by joining together the various pyrroles in the right order and what is needed for this one (and also, in fact, for another—the one in the north-east corner of the porphyrin) is a pyrrole with the correct substituents in positions 3 and 4, a methyl group in position 5, and a hydrogen atom at position 2. Position 2 must be free. Here is the molecule drawn somewhat more conveniently, together with the disconnection we have been using so far.

No doubt such a synthesis could be carried out but it is worth looking for alternatives for a number of reasons. We would prefer not to make a pyrrole with a free position at C2 as that would be very reactive and we know from Chapter 29 that we can reversibly block such a position with a t-butyl ester group. This gives us a very difficult starting material with four different carbonyl groups.

See p. 733 for a discussion of how to control pyrrole’s reactivity.
We have made a problem for ourselves by having two carbonyl groups next to each other. Could we escape from that by replacing one of them with an amine? We should then have an ester of an \( \alpha \) amino acid, a much more attractive starting material, and this corresponds to disconnecting just one of the C–N bonds.

At first we seem to have made no progress but just see what happens when we move the double bond round the ring into conjugation with the ketone. After all, it doesn't matter where the double bond starts out—we will always get the aromatic product.

Each of our two much simpler starting materials needs to be made. The keto-ester is a 1,5-dicarbonyl compound so it can be made by a conjugate addition of an enolate, a process greatly assisted by the addition of a second ester group.

The other compound is an amino-keto-ester and will certainly react with itself if we try to prepare it as a pure compound. The answer is to release it directly into the reaction mixture and this can be done by nitrosation and reduction (Chapter 20) of another stable enolate.

Zinc in acetic acid (Chapter 23) reduces the oxime to the amine and we can start the synthesis by doing the conjugate addition and then reducing the oxime in the presence of the keto-diester.

This reaction forms the required pyrrole in one step! First, the oxime is reduced to an amine, then the amino group forms an imine with the most reactive carbonyl group (the...
ketone) in the ketodiester. Finally, the very easily formed enamine cyclizes onto the other ketone.

This pyrrole synthesis is important enough to be given the name of its inventor—it is the Knorr pyrrole synthesis. Knorr himself made a rather simpler pyrrole in a remarkably efficient reaction. See if you can work out what is happening here.

Names for heterocyclic syntheses

Standard heterocyclic syntheses tend to have a name associated with them and it is simply not worthwhile learning these names. Few chemists use any but the most famous of them: we will mention the Knorr pyrrole synthesis, the Hantzsch pyridine synthesis, and the Fischer and Reissert indole syntheses. We did not mention that the synthesis of furans from 1,4-dicarbonyl compounds is known as the Feist–Benary synthesis, and there are many more like this. If you are really interested in these other names we suggest you consult a specialist book on heterocyclic chemistry.

How to make pyridines: the Hantzsch pyridine synthesis

The idea of coupling two keto-esters together with a nitrogen atom also works for pyridines except that an extra carbon atom is needed. This is provided as an aldehyde and another important difference is that the nitrogen atom is added as a nucleophile rather than an electrophile. These are features of the Hantzsch pyridine synthesis. This is a four-component reaction from simple starting materials.

You are hardly likely to understand the rationale behind this reaction from that diagram so let’s explore the details. The product of the reaction is actually the dihydropyridine, which has to be oxidized to the pyridine by a reagent such as HNO₃, Ce(IV), or a quinone.

The reaction is very simply carried out by mixing the components in the right proportions in ethanol. The presence of water does not spoil the reaction and the ammonia, or some added amine, ensures the slightly alkaline pH necessary. Any aldehyde can be used, even formaldehyde, and yields of the crystalline dihydropyridine are usually very good.

Arthur Hantzsch, 1857–1935, the ‘fiery stereochemist’ of Leipzig, was most famous for the work he did with Werner at the ETH in Zurich where in 1890 he suggested that oximes could exist in cis and trans forms.
This reaction is an impressive piece of molecular recognition by small molecules and writing a detailed mechanism is a bold venture. We can see that certain events have to happen, but which order they happen in is a matter of conjecture. The ammonia has to attack the ketone groups, but it would prefer to attack the more electrophilic aldehyde so this is probably not the first step. The enol or enolate of the keto-ester has to attack the aldehyde (twice!) so let us start there.

\[
\begin{align*}
\text{EtO}_2\text{C} & \text{O} \quad \text{EtO}_2\text{C} & \text{O} \\
\text{H} & \quad \text{H} \\
\end{align*}
\]

This adduct is in equilibrium with the stable enolate from the keto-ester and elimination now gives an unsaturated carbonyl compound. Such chemistry is associated with the aldol reactions we discussed in Chapter 26. The new enone has two carbonyl groups at one end of the double bond and is therefore a very good Michael acceptor (Chapter 25). A second molecule of enolate does a conjugate addition to complete the carbon skeleton of the molecule. Now the ammonia attacks either of the ketones and cyclizes on to the other. As ketones are more electrophilic than esters it is to be expected that ammonia will prefer to react there.

\[
\begin{align*}
\text{EtO}_2\text{C} & \text{R} & \text{CO}_2\text{Et} \\
\text{O} & \text{O} & \text{O} \\
\end{align*}
\]

The necessary oxidation is easy both because the product is aromatic and because the nitrogen atom can help to expel the hydrogen atom and its pair of electrons from the 4-position. If we use a quinone as oxidizing agent, both compounds become aromatic in the same step.

To recap this mechanism, the essentials are:
- aldol reaction between the aldehyde and the keto-ester
- Michael (conjugate) addition to the enone
- addition of ammonia to one ketone
- cyclization of the imine or enamine on to the other ketone

although several of the steps could happen in a different order.

The Hantzsch pyridine synthesis is an old discovery (1882) which sprang into prominence in the 1980s with the discovery that the dihydropyridine intermediates prepared from aromatic aldehydes are calcium channel-blocking agents and therefore valuable drugs for heart disease with useful effects on angina and hypertension.
So far, so good. But it also became clear that the best drugs were unsymmetrical—some in a trivial way such as felodipine but some more seriously such as Pfizer’s amlodipine. At first sight it looks as though the very simple and convenient Hantzsch synthesis cannot be used for these compounds.

Clearly, a modification is needed in which half of the molecule is assembled first. The solution lies in early work by Robinson, who made the very first enamines from keto-esters and amines. One half of the molecule is made from an enamine and the other half from a separately synthesized enone. We can use felodipine as a simple example.

Other syntheses of pyridines
The Hantzsch synthesis produces a reduced pyridine but there are many syntheses that go directly to pyridines. One of the simplest is to use hydroxylamine (NH$_2$OH) instead of ammonia as the nucleophile. Reaction with a 1,5-diketone gives a dihydropyridine but then water is lost and no oxidation is needed.

The example below shows how these 1,5-diketones may be quickly made by the Mannich (Chapter 26) and Michael (Chapter 25) reactions. Our pyridine has a phenyl substituent and a fused saturated ring. First we must disconnect to the 1,5-diketone.
Further disconnection reveals a ketone and an enone. There is a choice here and both alternatives would work well.

It is convenient to use the amine products of Mannich reactions ('Mannich bases') instead of the very reactive unsaturated ketones and we will continue with disconnection 'a'.

The synthesis is extraordinarily easy. The stable Mannich base is simply heated with the other ketone to give a high yield of the 1,5-diketone. Treatment of that with the HCl salt of NH₂OH in EtOH gives the pyridine directly, also in good yield.

Another direct route leads, as we shall now demonstrate, to pyridones. These useful compounds are the basis for nucleophilic substitutions on the ring (Chapter 29). We choose an example that puts a nitrile in the 3-position. This is significant because the role of nicotinamide in living things (Chapter 42) makes such products interesting to make. Aldol disconnection of a 3-cyano pyridone starts us on the right path. If we now disconnect the C–N bond forming the enamine on the other side of the ring we will expose the true starting materials. This approach is unusual in that the nitrogen atom that is to be the pyridine nitrogen is not added as ammonia but is already present in a molecule of cyanoacetamide.

The keto-aldehyde can be made by a simple Claisen ester condensation (Chapter 26) using the enolate of the methyl ketone with ethyl formate (HCO₂Et) as the electrophile. It actually exists as a stable enol, like so many 1,3-dicarbonyl compounds (Chapter 20).

In the synthesis, the product of the Claisen ester condensation is actually the enolate anion of the keto-aldehyde and this can be combined directly without isolation with cyanoacetamide to give the pyridone in the same flask.
What happens here is that the two compounds must exchange protons (or switch enolates if you prefer) before the aldol reaction occurs. Cyclization probably occurs next through C–N bond formation and, finally, dehydration is forced to give the Z alkene.

In planning the synthesis of a pyrrole or a pyridine from a dicarbonyl compound, considerable variation in oxidation state is possible. The oxidation state is chosen to make further disconnection of the carbon skeleton as easy as possible. We can now see how these same principles can be applied to pyrazoles and pyridazines.

**Pyrazoles and pyridazines from hydrazine and dicarbonyl compounds**

Disconnection of pyridazines reveals a molecule of hydrazine and a 1,4-diketone with the proviso that, just as with pyridines, the product will be a dihydropyrazine and oxidation will be needed to give the aromatic compound. As with pyridines, we prefer to avoid the cis double bond problem.

As an example we can take the cotton herbicide made by Cyanamid. Direct removal of hydrazine would require a problematic cis double bond in the starting material.

If we remove the double bond first, a much simpler compound emerges. Note that this is a ketoester rather than a diketone.

When hydrazine is added to the keto-ester an imine is formed with the ketone but acylation occurs at the ester end to give an amide rather than the imino-ester we had designed.
Aromatization with bromine gives the aromatic pyridazolone by bromination and dehydrobromination, and now we invoke the nucleophilic substitution reactions introduced in Chapter 29. First we make the chloride with POCl₃ and then displace with methanol.

The five-membered ring pyrazoles are even simpler as the starting material is a 1,3-dicarbonyl compound available from the aldol or Claisen ester condensations.

**Chemistry hits the headlines—Viagra**

In 1998 chemistry suddenly appeared in the media in an exceptional way. Normally not a favourite of TV or the newspapers, chemistry produced a story with all the right ingredients—sex, romance, human ingenuity—and all because of a pyrazole. In the search for a heart drug, Pfizer uncovered a compound that allowed impotent men to have active sex lives. They called it Viagra. The molecule contains a sulfonamide and a benzene ring as well as the part that interests us most—a bicyclic aromatic heterocyclic system of a pyrazole fused to a pyrimidine. We shall discuss in detail how Pfizer made this part of the molecule and just sketch in the rest. The sulfonamide can be made from the sulfonic acid that can be added to the benzene ring by electrophilic aromatic sulfonation (Chapter 21).

Inspection of what remains reveals that the carbon atom in the heterocycles next to the benzene ring (marked with an orange blob) is at the oxidation level of a carboxylic acid. If, therefore, we disconnect both C—N bonds to this atom we will have two much simpler starting materials.
The aromatic acid is available and we need consider only the pyrazole (the core pyrazole ring in black in the diagram). The aromatic amino group can be put in by nitration and reduction, and the amide can be made from the corresponding ester. This leaves a carbon skeleton, which must be made by ring synthesis.

Following the methods we have established so far in this chapter, we can remove the hydrazine portion to reveal a 1,3-dicarbonyl compound. In fact, this is a tricarbonyl compound, a diketo-ester, because of the ester already present and it contains 1,2-, 1,3-, and 1,4-dicarbonyl relationships. The simplest synthesis is by a Claisen ester condensation and we choose the disconnection so that the electrophile is a reactive (oxalate) diester that cannot enolize. The only control needed will then be in the enolization of the ketone.

The Claisen ester condensation gives the right product just by treatment with base. The reasons for this are discussed in Chapter 26. We had then planned to treat the keto-diester with methylhydrazine but there is a doubt about the regioselectivity of this reaction—the ketones are more electrophilic than the ester all right, but which ketone will be attacked by which nitrogen atom?

We have already seen the solution to this problem in Chapter 29. If we use symmetrical hydrazine, we can deal with the selectivity problem by alkylation. Dimethyl sulfate turns out to be the best reagent.

The stable pyrazole acid from the hydrolysis of this ester is a key intermediate in Viagra production. Nitration can occur only at the one remaining free position and then amide formation and reduction complete the synthesis of the amino pyrazole amide ready for assembly into Viagra.

The alkylation is regioselective because the methylated nitrogen must become the pyrrole-like nitrogen atom and the molecule prefers the longest conjugated system involving that nitrogen and the ester.
The rest of the synthesis can be summarized very briefly as it mostly concerns material outside the scope of this chapter. You might like to notice how easy the construction of the second heterocyclic ring is—the nucleophilic attack of the nitrogen atom of one amide on to the carbonyl of another would surely not occur unless the product were an aromatic heterocycle.

Pyrimidines can be made from 1,3-dicarbonyl compounds and amidines

In Chapter 29 we met some compounds that interfere in folic acid metabolism and are used as antibacterial agents. One of them was trimethoprim and it contains a pyrimidine ring (black on the diagram). We are going to look at its synthesis briefly because the strategy used is the opposite of that used with the pyrimidine ring in Viagra. Here we disconnect a molecule of guanidine from a 1,3-dicarbonyl compound.

The 1,3-dicarbonyl compound is a combination of an aldehyde and an amide but is very similar to a malonic ester so we might think of making this compound by alkylation of that stable enolate (Chapter 25) with the convenient benzylic bromide.
The alkylation works fine but it turns out to be better to add the aldehyde as an electrophile (cf. the pyridone synthesis on p. 766) rather than try to reduce an ester to an aldehyde. The other ester is already at the right oxidation level.

Condensation with ethyl formate (HCO₂Et) and cyclization with guanidine gives the pyrimidine ring system but with an OH instead of the required amino group. Aromatic nucleophilic substitution the pyridone style from Chapter 29 gives trimethoprim.

Unsymmetrical nucleophiles lead to selectivity questions

The synthesis of thiazoles is particularly interesting because of a regioselectivity problem. If we try out the two strategies we have just used for pyrimidines, the first requires the reaction of a carboxylic acid derivative with a most peculiar enamine that is also a thioenol. This does not look like a stable compound.

The alternative is to disconnect the C–N and C–S bonds on the other side of the heteroatoms. Here we must be careful what we are about or we will get the oxidation state wrong. We shall do it step by step to make sure. We can rehydrate the double bond in two ways. We can first try putting the OH group next to nitrogen.

Or we can rehydrate it the other way round, putting the OH group next to the sulfur atom, and disconnect in the same way. In both cases we require an electrophilic carbon atom at the alcohol oxidation level and one at the aldehyde or ketone oxidation level. In other words we need an α-haloketone.
The nucleophile is the same in both cases and it is an odd-looking molecule. That is, until we realize that it is just a tautomer of a thioamide. Far from being odd, thioamides are among the few stable thiocarbonyl derivatives and can be easily made from ordinary amides with $P_2S_5$, or Lawesson’s reagent.

So the only remaining question is: when thioamides combine with $\alpha$-haloketones, which nucleophilic atom (N or S) attacks the ketone, and which atom (N or S) attacks the alkyl halide? Carbonyl groups are ‘hard’ electrophiles—their reactions are mainly under charge control and so they react best with basic nucleophiles (Chapter 10). Alkyl halides are ‘soft’ electrophiles—their reactions are mainly under frontier orbital control and they react best with large uncharged nucleophiles from the lower rows of the periodic table. The ketone reacts with nitrogen and the alkyl halide with sulfur.

Fentiazac, a non-steroidal anti-inflammatory drug, is a simple example. Disconnection shows that we need thiobenzamide and an easily made $\alpha$-haloketone (easily made because the ketone can enolize on this side only—see Chapter 20).

The synthesis involves heating these two compounds together and the correct thiazole forms easily with the double bonds finding their right positions in the product—the only positions for a stable aromatic heterocycle.

**Isoxazoles are made from hydroxylamine or by cycloaddition**

The two main routes for the synthesis of isoxazoles are (a) the attack of hydroxylamine ($\text{NH}_2\text{OH}$) on diketones and (b) a reaction of nitrile oxides called a 1,3-dipolar cycloaddition. They thus form a link between the strategy we have been discussing (cyclization of a nucleophile with two heteroatoms and a compound with two electrophilic carbon atoms) and the next strategy—cycloaddition reactions.

Simple symmetrical isoxazoles are easily made by the hydroxylamine route. If $R^1 = R^3$, we have a symmetrical and easily prepared 1,3-diketone as starting material. The central $R^2$ group can be inserted by alkylation of the stable enolate of the diketone (Chapter 25).
When $R_1 \neq R_3$, we have an unsymmetrical dicarbonyl compound and we must be sure that we know which way round the reaction will proceed. The more nucleophilic end of $NH_2OH$ will attack the more electrophilic carbonyl group. It seems obvious that the more nucleophilic end of $NH_2OH$ will be the nitrogen atom but that depends on the pH of the solution. Normally, hydroxylamine is supplied as the crystalline hydrochloride salt and a base of some kind added to give the nucleophile. The relevant $pK_a$'s are shown in the margin. Bases such as pyridine or sodium acetate produce some of the reactive neutral $NH_2OH$ in the presence of the less reactive cation, but bases such as NaOEt produce the anion. Reactions of keto-aldehydes with acetate-buffered hydroxylamine usually give the isoxazole from nitrogen attack on the aldehyde as expected.

Modification of the electrophile may also be successful. Reaction of hydroxylamine with 1,2,4-diketo-esters usually gives the isoxazole from attack of nitrogen at the more reactive keto group next to the ester.

A clear demonstration of selectivity comes from the reactions of bromoenones. It is not immediately clear which end of the electrophile is more reactive but the reactions tell us the answer.

The alternative approach to isoxazoles relies on the reaction of nitrile oxides with alkynes. We shall see in Chapter 34 that there are two good routes to these reactive compounds, the $\gamma$-elimination of chlorooximes or the dehydration of nitroalkanes.

A few nitrile oxides are stable enough to be isolated (those with electron-withdrawing or highly conjugating substituents, for example) but most are prepared in the presence of the alkyne by one of these methods because otherwise they dimerize rapidly. Both methods of forming nitrile oxides are compatible with their rapid reactions with alkynes. With aryl alkynes the reaction is usually clean and regioselective.

The reaction forms the five-membered ring in a single step: it is a cycloaddition, in which the alkyne is using its HOMO to attack the LUMO of the nitrile oxide (see Chapter 34 for an explanation). If the alkyne has an electron-withdrawing group, mixtures of isomers are usually formed as the HOMO of the nitrile oxide also attacks the LUMO of the alkyne. Intramolecular reactions are usually clean regardless of the preferred electronic orientation if...
the tether is too short to allow any cyclization except one. In this example, even the more favourable orientation looks very bad because of the linear nature of the reacting species, but only one isomer is formed.

\[
\begin{align*}
R^1 - & N = O \\
\text{EtO}_2C - & \text{H}_2C = \text{O} - \text{CO}_2\text{Et} \\
\text{O} - & \text{N} + \\
\end{align*}
\]

**Tetrazoles and triazoles are also made by cycloadditions**

Disconnection of tetrazoles with a 1,3-dipolar cycloaddition in mind is easy to see once we realize that a nitrile (RCN) is going to be one of the components. It can be done in two ways: disconnection of the neutral compound would require the dangerous hydrazoic acid (HN₃) as the dipole but the anion disconnects directly to azide ion.

\[
\begin{align*}
\text{HN}_2 & - \text{N}_2 \\
\text{R} & \text{N} \\
\end{align*}
\]

Unpromising though this reaction may look, it actually works well if an ammonium chloride-buffered mixture of sodium azide and the nitrile is heated in DMF. The reagent is really ammonium azide and the reaction occurs faster with electron-withdrawing substituents in R. In the reaction mixture, the anion of the tetrazole is formed but neutralization with acid gives the free tetrazole.

\[
\begin{align*}
\text{RCN} & \xrightarrow{\text{NaN}_3, \text{NH}_4\text{Cl}} \text{R} - \text{N} \\
\text{LiCl, DMF, 100 °C} & \rightarrow \text{R} - \text{N} \xrightarrow{\text{H}^+} \text{N} - \text{N} \xrightarrow{\text{H}^+} \text{N} - \text{N} \xrightarrow{\text{H}^+} \text{N} - \text{N} \\
\end{align*}
\]

As nitriles are generally readily available this is the main route to simple tetrazoles. More complicated ones are made by alkylation of the product of a cycloaddition. The tetrazole substitute for indomethacin that we mentioned in Chapter 29 is made by this approach. First, the nitrile is prepared from the indole. The 1,3-dipolar cycloaddition works well by the azide route we have just discussed, even though this nitrile will form an ‘enol’ rather easily. Finally, the indole nitrogen atom must be acylated. The tetrazole is more acidic so it is necessary to form a dianion to get reaction at the right place. The usual rule is followed (see Chapter 23)—the second anion formed is less stable and so it reacts first.

\[
\begin{align*}
\text{Me} & \xrightarrow{\text{MeNH}_2, \text{CH}_2=\text{O}} \xrightarrow{\text{MeCN}} \xrightarrow{\text{NaN}_3, \text{NH}_4\text{Cl}} \text{Me} \\
\text{Mannich} & \text{LiCl, DMF, 100 °C} \rightarrow \text{Me} \\
\end{align*}
\]
The synthesis of the anti-inflammatory drug broperamole illustrates modification of a tetra-
zole using its anion. The tetrazole is again constructed from the nitrile—it’s an aromatic
nitrile with an electron-withdrawing substituent so this will be a good reaction.
Conjugate addition to acrylic acid (Chapter 22) occurs to give the other tautomer to the one
we have drawn. The anion intermediate is, of course, delocalized and can react at any of the
nitrogen atoms. Amide formation completes the synthesis of broperamole.

One of the best reactions of all is the related cycloaddition of a substituted azide to an
alkyne. Just mixing together and heating an azide and an alkyne will give a triazole, but often
as a mixture of two regioisomers.

However, a simple addition to the reaction mixture improves the situation hugely: a cata-
lytic amount of Cu(I), often made in situ by adding CuSO₄ and a mild reducing agent, makes
the reaction much faster and gives the 1,4-disubstituted triazole selectively. The work of
Sharpless has turned this reaction into not only a very powerful way of making triazoles, but
also a very simple way of linking two otherwise relatively unreactive molecules together—the
reaction even works in water.

**The Fischer indole synthesis**

You are about to see one of the great inventions of organic chemistry. It is a remarkable reac-
tion, amazing in its mechanism, and it was discovered in 1883 by one of the greatest organic
chemists of all, Emil Fischer. Fischer had earlier discovered phenylhydrazine (PhNHNH₂)
and, in its simplest form, the Fischer indole synthesis occurs when phenylhydrazine is heated
in acidic solution with an aldehyde or ketone.
The first step in the mechanism is formation of the phenylhydrazone (the imine) of the ketone. This can be isolated as a stable compound (Chapter 11).

\[
\text{phenylhydrazine} + \text{ketoacid} \rightarrow \text{cyclohexanone phenylhydrazone}
\]

The hydrazone then needs to tautomerize to the enamine, and now comes the key step in the reaction. The enamine can rearrange with formation of a strong C–C bond and cleavage of the weak N–N single bond by moving electrons round a six-membered ring.

Next, re-aromatization of the benzene ring (by proton transfer from carbon to nitrogen) creates an aromatic amine that immediately attacks the other imine. This gives an aminal, the nitrogen equivalent of an acetal.

Finally, acid-catalysed decomposition of the aminal in acetal fashion with expulsion of ammonia allows the loss of a proton and the formation of the aromatic indole.

This is admittedly a complicated mechanism but if you remember the central step—the rearrangement of the enamine—the rest should fall into place. The key point is that the C–C bond is established at the expense of a weak N–N bond. Naturally, Fischer had no idea of any of the steps in the mechanism. He was sharp enough to see that something remarkable had happened and skilful enough to find out what it was.

The Fischer method is the main way of making indoles, but it is not suitable for them all. We need now to consider its applicability to various substitution patterns. If the carbonyl compound can enolize on one side only, as is the case with an aldehyde, then the obvious product is formed.
If the benzene ring has only one ortho position, then again cyclization must occur to that position. Other substituents on the ring are irrelevant.

Another way to secure a single indole as product from the Fischer indole synthesis is to make sure the reagents are symmetrical. These two examples should make plain the types of indole available from symmetrical starting materials.

The substitution pattern of the first example is particularly important as the neurotransmitter serotonin is an indole with a hydroxyl group in the 5-position, and many important drugs follow that pattern. Sumatriptan (marketed as Imigran, the migraine treatment) is an analogue of serotonin, whose synthesis starts with the formation of a diazonium salt (Chapter 22) from the aniline shown below. Nitrosation gives the diazonium salt, and reduction with SnCl₂ and HCl returns the salt of the phenylhydrazine.

The required aldehyde (3-cyanopropanal) is added as an acetal to prevent self-condensation. The acidic conditions release the aldehyde, which forms the phenylhydrazone, ready for the next step.

The Fischer indole synthesis itself is catalysed in this case by polyphosphoric acid (PPA), a sticky gum based on phosphoric acid (H₃PO₄) but dehydrated so that it contains some oligomers. It is often used as a catalyst in organic reactions and residues are easily removed in water.

All that remains is to introduce the dimethylamino group. The nitrile is reduced by hydrogenation and the two methyl groups added by reductive amination with formaldehyde. The reducing agent is formic acid, and the reaction works by sequential formation...
and reduction of an imine, followed by an iminium formation and reduction to introduce the second methyl group.

For some indoles it is necessary to control regioselectivity with unsymmetrical carbonyl compounds. Ondansetron, the anti-nausea compound that is used to help cancer patients take larger doses of antitumour compounds than was previously possible, is an example. It contains an indole and an imidazole ring.

The 1,3 relationship between C–N and C–O suggests a Mannich reaction to add the imidazole ring (Chapters 26 and 28), and that disconnection reveals an indole with an unsymmetrical right-hand side, having an extra ketone group. Fischer disconnection will reveal a diketone as partner for phenylhydrazine. We shall leave aside for the moment when to add the methyl group to the indole nitrogen.

The diketone has two identical carbonyl groups and will enolize (or form an enamine) exclusively towards the other ketone. The phenylhydrazone therefore forms only the enamine we want.

In this case, the Fischer indole reaction was catalysed by a Lewis acid, ZnCl₂, and base-catalysed methylation followed. The final stages are summarized below.

In the worst case, there is no such simple distinction between the two sites for enamine formation and we must rely on other methods of control. The non-steroidal anti-inflammatory drug indomethacin is a good example. Removing the N-acyl group reveals an indole with substituents in both halves of the molecule.
The benzene ring portion is symmetrical and is ideal for the Fischer synthesis but the right-hand half must come from an unsymmetrical open-chain keto-acid. Is it possible to control such a synthesis?

The Fischer indole is acid-catalysed so we must ask: on what side of the ketone is enolization (and therefore enamine formation) expected in acid solution? The answer (see Chapter 20) is away from the methyl group and into the alkyl chain. This is what we want and the reaction does indeed go this way. In fact, the tert-butyl ester is used instead of the free acid.

Acylation at the indole nitrogen atom is achieved with acid chloride in base and removal of the tert-butyl ester gives free indomethacin.

There are many other indole syntheses but we will give a brief mention to only one other, which allows the synthesis of indoles with a different substitution pattern in the benzene ring. If you like names, you may call it the Reissert synthesis, and this is the basic reaction.

Ethoxide is a strong enough base to remove a proton from the methyl group, delocalizing the negative charge into the nitro group. The anion then attacks the reactive diester (diethyl oxalate) and is acylated by it.
The rest of the synthesis is more straightforward: the nitro group can be reduced to an amine, which immediately forms an enamine by intramolecular attack on the more reactive carbonyl group (the ketone) to give the aromatic indole. Since the nitro compound is made by nitration of a benzene ring, the preferred symmetry is very different from that needed for the Fischer synthesis. Nitration of \( \text{para-xylene} \) (1,4-dimethylbenzene) is a good example.

The ester products we have been using so far can be hydrolysed and decarboxylated by the mechanism described in the last chapter if a free indole is required. In any case, it is not necessary to use diethyl oxalate as the electrophilic carbonyl compound. The synthesis below, using the acetal of DMF as the electrophile, forms part of the synthesis of the strange antibiotic chuangxinmycin.

**Quinolines and isoquinolines**

Quinoline forms part of the structure of quinine, the malaria remedy found in cinchona bark and known since the time of the Incas. The quinoline in quinine has a 6-MeO substituent and a side chain attached to C4. In discussing the synthesis of quinolines, we will be particularly interested in this pattern. This is because the search for anti-malarial compounds continues and other quinolines with similar structures are among the available anti-malarial drugs.

We shall also be very interested in quinolones, analogous to pyridones, with carbonyl groups at positions 2 and 4, as these are useful antibiotics. A simple example is pefloxacin, which has typical 6-F and 7-piperazine substituents.
When we consider the synthesis of a quinoline, the obvious disconnections are, first, the C–N bond in the pyridine ring and, then, the C–C bond that joins the side chain to the benzene ring. We will need a three-carbon (C₃) synthon, electrophilic at both ends, which will yield two double bonds after incorporation. The obvious choice is a 1,3-dicarbonyl compound.

![imine](image)

The choice of an aromatic amine is a good one as the NH₂ group reacts well with carbonyl compounds and it activates the ortho position to electrophilic attack. However, the dialdehyde is malonic dialdehyde, a compound that does not exist, so some alternative must be found. If the quinoline is substituted in the 2- and 4-positions this approach looks better.

![imine](image)

The initially formed imine will tautomerize to a conjugated enamine and cyclization now occurs by electrophilic aromatic substitution. The enamine will normally prefer to adopt the first configuration shown in which cyclization is not possible, and (perhaps for this reason or perhaps because it is difficult to predict which quinoline will be formed from an unsymmetrical 1,3-dicarbonyl compound) this has not proved a very important quinoline synthesis. However, the synthetic plan is sound, and we shall describe two important variants on this theme, one for quinolines and one for quinolones.

![imine](image)

In the synthesis of pyridines it proved advantageous to make a dihydropyridine and oxidize it to a pyridine afterwards. The same idea works well in probably the most famous quinoline synthesis, the Skraup reaction. The diketone is replaced by an unsaturated carbonyl compound so that the quinoline is formed regiospecifically. The first step is conjugate addition of the amine. Under acid catalysis the ketone now cyclizes in the way we have just described to give a dihydroquinoline after dehydration. Oxidation to the aromatic quinoline is an easy step accomplished by many possible oxidants.
Traditionally, the Skraup reaction was carried out by mixing everything together and letting it rip. A typical mixture to make a quinoline without substituents on the pyridine ring would be the aromatic amine, concentrated sulfuric acid, glycerol, and nitrobenzene all heated up in a large flask at over 100 °C with a wide condenser.

The glycerol was to provide acrolein (CH$_2$=CH-CHO) by dehydration, the nitrobenzene was to act as oxidant, and the wide condenser...? All too often Skraup reactions did let rip—with destructive results. A safer approach is to prepare the conjugate adduct first, cyclize it in acid solution, and then oxidize it with one of the reagents we described for pyridine synthesis, particularly quinones such as DDQ.

The more modern style of Skraup synthesis is used to make 8-quinolinol or 'oxine'. ortho-Aminophenol has only one free position ortho to the amino group and is very nucleophilic, so acrolein can be used in weak acid with only a trace of strong acid. Iron(III) is the oxidant, with a bit of boric acid for luck, and the yield is excellent.

Quinolones also come from anilines by cyclization to an ortho position

The usual method for making quinolone antibiotics is possible because they all have a carboxylic acid in the 3-position. The disconnection we used for quinoline suggests a rather unstable malonic ester derivative as starting material.

In fact, the enol ether of this compound is easily made from diethyl malonate and ethyl orthoformate [HC(OEt)$_3$]. The aromatic amine reacts with this compound by an addition–elimination sequence, giving an enamine that cyclizes on heating. This time the geometry of the enamine is not a concern.
For examples of quinolone antibiotics we can choose ofloxacin, whose synthesis was discussed in detail in Chapter 22, and rosoxacin, whose synthesis is discussed below. Both molecules contain the same quinolone carboxylic acid framework, outlined in black, with another heterocyclic system at position 7 and various other substituents here and there.

To make rosoxacin two heterocyclic systems must be constructed. Workers at the pharmaceutical company Sterling decided to build the pyridine in an ingenious version of the Hantzsch synthesis using acetylenic esters on 3-nitrobenzaldehyde. The ammonia was added as ammonium acetate. Oxidation with nitric acid made the pyridine, hydrolysis of the esters and decarboxylation removed the acid groups, and reduction with Fe(II) and HCl converted the nitro group into the amino group required for the quinolone synthesis.

Now the quinolone synthesis can be executed with the same reagents we used before and all that remains is ester hydrolysis and alkylation at nitrogen. Notice that the quinolone cyclization could in theory have occurred in two ways as the two positions ortho to the amino group are different. In practice cyclization occurs away from the pyridine ring as the alternative quinolone would be impossibly crowded.

Since quinolones, like pyridones, can be converted into chloro-compounds with POCl₃, they can be used in nucleophilic substitution reactions to build up more complex quinolines.
We will give just one important synthesis of isoquinolines here. It is a synthesis of a dihydroisoquinoline by what amounts to an intramolecular Vilsmeier reaction in which the electrophile is made from an amide and POCl₃. Oxidation (in this case a dehydrogenation with Pd(0)) gives the quinoline.

More heteroatoms in fused rings mean more choice in synthesis

The imidazo-pyridazine ring system forms the basis for a number of drugs in human and animal medicine. The synthesis of this system uses the chemistry discussed in Chapter 29 to build the pyridazine ring. There we established that it was easy to make dichloropyridazines and to displace the chlorine atoms one by one with different nucleophiles. Now we will move on from these intermediates to the bicyclic system.

A 2-bromo-acid derivative is the vital reagent. It reacts at the amino nitrogen atom with the carbonyl group and at the pyridazine ring nitrogen atom with the alkyl halide. This is the only way the molecule can organize itself into a ten-electron aromatic system.

In Chapter 29 we also gave the structure of timolol, a thiadiazole-based β-blocker drug for reduction of high blood pressure. This compound has an aromatic 1,2,5-thiadiazole ring system and a saturated morpholine as well as an aliphatic side chain. Its synthesis relies on ring formation by rather a curious method followed by selective nucleophilic substitution, rather in the style of the last synthesis. The aromatic ring is made by the action of S₂Cl₂ on ‘cyanamide’.

This reaction must start by attack of the amide nitrogen on the electrophilic sulfur atom. Cyclization cannot occur while the linear nitrile is in place so chloride ion (from disproportionation of CIS⁻) must first attack CN. Thereafter cyclization is easy.
Reaction with epichlorohydrin followed by amine displacement puts in one of the side chains and nucleophilic substitution with morpholine on the ring completes the synthesis.

Summary: the three major approaches to the synthesis of aromatic heterocycles

We end this chapter with summaries of the three major strategies in the synthesis of heterocycles:

- ring construction by ionic reactions
- ring construction by cycloadditions
- modification of existing rings by electrophilic or nucleophilic aromatic substitution or by lithiation and reaction with electrophiles.

We will summarize the different applications of these strategies, and also suggest cases for which each strategy is not suitable. This section revises material from Chapter 29 as well since most of the ring modifications appear there.

Ring construction by ionic cyclization

The first strategy you should try out when faced with the synthesis of an aromatic heterocyclic ring is the disconnection of bonds between the heteroatom or atoms and carbon, with the idea of using the heteroatoms as nucleophiles and the carbon fragment as a double electrophile.

Heterocycles with one heteroatom

five-membered rings

- pyrroles, thiophenes, and furans ideally made by this strategy from 1,4-dicarbonyl compounds
six-membered rings
• pyridines made by this strategy from 1,5-dicarbonyl compounds with oxidation

\[
\begin{array}{c}
\text{R}_1 \text{O} \text{R}_2 \\
\text{O} \text{R}_1 \text{O}
\end{array}
\xrightarrow{\text{NH}_3}
\begin{array}{c}
\text{N} \text{R}_1 \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\xrightarrow{[O]}
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\]
dihydropyridines pyridines

Heterocycles with two adjacent heteroatoms
five-membered rings
• pyrazoles and isoxazoles ideally made by this strategy from 1,3-dicarbonyl compounds

\[
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\xrightarrow{\text{H}_2\text{N} \xrightarrow{\text{NH}_2}}
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\text{pyrazoles}

\[
\begin{array}{c}
\text{R}_1 \text{O} \text{R}_2 \\
\text{O} \text{R}_1 \text{O}
\end{array}
\xrightarrow{\text{HO} \xrightarrow{\text{NH}_2}}
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\text{isoxazoles}

\[
\begin{array}{c}
\text{R}_1 \text{O} \text{R}_2 \\
\text{O} \text{R}_1 \text{O}
\end{array}
\xrightarrow{\text{HS} \xrightarrow{\text{NH}_2}}
\begin{array}{c}
\text{R}_1 \text{S} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{S}
\end{array}
\text{isothiazoles}
\]

Note. This strategy is not suitable for isothiazoles as ‘thiolamine’ does not exist

six-membered rings
• pyrimidines ideally made by this strategy from 1,3-dicarbonyl compounds

\[
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\xrightarrow{\text{NH}_2 \xrightarrow{\text{NH}_2}}
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\xrightarrow{[O]}
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\]
an amidine a pyrimidine

Heterocycles with two non-adjacent heteroatoms
five-membered rings
• imidazoles and thiazoles ideally made by this strategy from α-halocarbonyl compound

\[
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\xrightarrow{\text{R}_1 \text{S} \text{Br} \xrightarrow{\text{R}_3}}
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\text{a thiazole}

\[
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\xrightarrow{\text{R}_1 \text{N} \text{NH}_2 \xrightarrow{\text{Br} \text{R}_3}}
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\text{an imidazole}
\]

Note. This strategy is not suitable for oxazoles as amides are not usually reactive enough: cyclization of acylated carbonyl compounds is usually preferred

\[
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\xrightarrow{\text{HN} \xrightarrow{\text{H}^\text{+}}}
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\text{an oxazole}
\]

six-membered rings
• pyrimidines ideally made by this strategy from 1,3-dicarbonyl compounds

\[
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\xrightarrow{\text{R}_1 \text{N} \text{R}_3 \xrightarrow{\text{R}_1}}
\begin{array}{c}
\text{R}_1 \text{N} \text{R}_2 \\
\text{R}_1 \text{R}_2 \text{N}
\end{array}
\]
an amidine a pyrimidine
Ring construction by cycloadditions

1,3-dipolar cycloaddition reactions

- ideal for the construction of isoxazoles, 1,2,3-triazoles, and tetrazoles

\[
\begin{align*}
\text{1,3-dipolar cycloaddition} & \quad \text{heat} \\
\text{an isoxazole} & \\
\end{align*}
\]

\[
\begin{align*}
\text{1,3-dipolar cycloaddition} & \quad \text{heat} \\
a \text{1,2,3-triazole} & \\
\end{align*}
\]

\[
\begin{align*}
\text{1,3-dipolar cycloaddition} & \quad \text{heat} \\
a \text{tetrazole} & \\
\end{align*}
\]

...or sigmatropic rearrangements

- a special reaction that is the vital step of the Fischer indole synthesis

Ring modification

Electrophilic aromatic substitution

- works very well on pyrroles, thiophenes, and furans, where it occurs best in the 2- and 5-positions and nearly as well in the 3- and 4-positions
- often best to block positions where substitution not wanted
- works well for indole—occurs only in the 3-position but the electrophile may migrate to the 2-position

Nucleophilic aromatic substitution

- works particularly well for pyridine and quinoline where the charge in the intermediate can rest on nitrogen
• especially important for pyridones and quinolones with conversion to the chloro-compound and displacement of chlorine by nucleophiles and, for quinolines, displacement of fluorine atoms on the benzene ring

\[ \text{N} \quad \text{H} \quad \text{O} \quad \text{N} \quad \text{Cl} \quad \text{Nu}^\ominus \]

• works well for the six-membered rings with two nitrogens (pyridazines, pyrimidines, and piperazines) in all positions

\[ \text{F} \quad \text{N} \quad \text{H} \quad \text{O} \quad \text{Nu} \]

Lithiation and reaction with electrophiles

• works well for pyrrole (if NH blocked), thiophene, or furan next to the heteroatom. Exchange of Br or I for Li works well for most electrophiles providing any acidic hydrogens (including the NH in the ring) are blocked

\[ \text{Z} = \text{NR}, \text{S}, \text{or O} \quad \text{BuLi} \quad \text{Z} \quad \text{E}^\ominus \]

Introduction

Rings make a difference to the way molecules react and the ways they can be made, and we have just devoted two chapters to the reactions and synthesis of flat, aromatic heterocycles. In this chapter and the one that follows we shall continue to look at rings, but not flat aromatic ones. Once you put saturated atoms into rings the rings become flexible and display interesting chemical features. We introduced ways of talking about conformation in rings in Chapter 16, and we will revisit ideas from that chapter—in particular we will build on the idea that rings make it easier to think about stereochemistry because they restrict the number of conformations a molecule can adopt. We will also introduce a theme which we develop over the next few chapters of the book: stereoselectivity—how to make single diastereoisomers of a product.

It may seem strange that heterocycles—rings containing not just carbon atoms, but oxygen, nitrogen, or sulfur as well—deserve three whole chapters, but you will soon see that this is justified both by the sheer number and variety of heterocycles that exist and by their special chemical features. We dealt with the special stereochemical features of aromatic heterocycles...
in the last two chapters, in particular their distinctive reactivity, stability, and ease of synthesis. Some examples of saturated heterocycles, a few of which may be familiar to you, are shown below.

The saturated heterocyclic rings are shown in black, and names for the most important ring types are given: some (like piperidine, morpholine) you will need to remember; others (tetrahydrofuran, pyrrolidine) are more obviously derived from the names for aromatic heterocycles you met in the last chapter. Some of these compounds (nicotine, coniine, cocaine) are plant products falling into the class called alkaloids, which are discussed in Chapter 42. Another important class of saturated heterocycles, sugars, will also appear in Chapter 42.

But what are the ‘special chemical features’ of saturated heterocycles? Putting a heteroatom into a ring does two important things, and these lead to the most important new topics in this chapter.

- Firstly, the heteroatom makes the ring easy to make by a ring-closing reaction, or (in some cases) easy to break by a ring-opening reaction. Closing and opening reactions of rings are subject to constraints that you will need to know about, and the principles that govern these reactions are discussed later in the chapter.
- Secondly, the ring fixes the orientation of the heteroatom—and, in particular, the orientation of its lone pairs—relative to the atoms around it. This has consequences for the reactivity and conformation of the heterocycle which can be explained using the concept of stereoelectronics.

*Stereoelectronic effects are chemical consequences of the arrangement of orbitals in space.*

**Reactions of saturated heterocycles**

**Saturated nitrogen heterocycles: amines, but more nucleophilic**

In many reactions the simple saturated nitrogen heterocycles—piperidine, pyrrolidine, piperazine, and morpholine—behavior simply as secondary amines that happen to be cyclic.
They do the sorts of things that other amines do, acting as nucleophiles in addition and substitution reactions. Morpholine, for example, is acylated by 3,4,5-trimethoxybenzoyl chloride to form the tranquillizer and muscle relaxant trimetozine, and N-methylpiperazine can be alkylated in an $S_N1$ reaction with diphenylmethyl chloride to give the travel-sickness drug cyclizine.

The addition of pyrrolidine to aldehydes and ketones is a particularly important reaction because it leads to enamines, the valuable enol equivalents discussed in Chapter 25.

Enamines formed from pyrrolidine and piperidine are particularly stable because pyrrolidine and piperidine are rather more nucleophilic than comparable acyclic amines such as diethylamine. This is a general feature of cyclic amines (and cyclic ethers, too, as you will see shortly), and is a steric effect. The alkyl substituents, being tied back into a ring, are held clear of the nucleophilic lone pair, allowing it to approach an electrophile without hindrance. This effect is well illustrated by comparing the rates of reaction of methyl iodide with three amines—tertiary this time. The two cyclic compounds are bridged—quinuclidine is a bridged piperidine while the diamine known as DABCO (1,4-diazabicyclo[2.2.2]octane) is a bridged piperazine. The table below shows the relative rates, along with $pK_a$ values, for triethylamine, quinuclidine, and DABCO.

Quinuclidine and DABCO are 40–60 times more reactive than triethylamine. This is again due to the way the ring structures keep the nitrogen’s substituents away from interfering with the lone pair as it attacks the electrophile. You should contrast the effect that the cyclic structure has on the basicity of the amines: none! Triethylamine and quinuclidine are equally basic and, as you can see in the margin, so (more or less) are diethylamine, dibutylamine, and piperidine. A proton is so small that it cares very little whether the alkyl groups are tied back or not.

Much more important in determining $pK_a$ is how electron-rich the nitrogen is, and this is the cause of the glaring discrepancy between the basicity of quinuclidine and that of DABCO, or between the basicities of piperidine ($pK_a$ 11.2) and morpholine ($pK_a$ 9.8) or piperazine ($pK_a$ 8.4). The extra heteroatom, through an inductive effect, withdraws electron density from the nitrogen atom, making it less nucleophilic and less basic. In this sense, morpholine can be a very useful base, less basic than triethylamine but somewhat more so than pyridine ($pK_a$ 5.2). Notice how much lower is the second $pK_a$ (that is, the $pK_a$ for protonation of the second nitrogen) of the diamines DABCO and piperazine: the protonated nitrogen of the monoprotonated amine withdraws electrons very effectively from the unprotonated one.

The Baylis–Hillman reaction

One of the most important uses of DABCO is in the Baylis–Hillman reaction, discovered in 1972 by two chemists at the Celanese Corporation in New York. Their reaction is a modification of the aldol reaction (Chapter 26), except that instead of the enolate being formed by deprotonation it is formed by conjugate addition. You have seen the enolate products of conjugate addition being trapped by alkylating agents in Chapter 25, but in the Baylis–Hillman reaction the electrophile is an aldehyde and is present right from the start of the reaction, which is done just by stirring the components at room temperature. Here is a typical example.

The reaction starts with the (relatively nucleophilic) DABCO undergoing conjugate addition to ethyl acrylate. This will form an enolate that can then attack the acetaldehyde in an aldol reaction.

E1cB eliminations often follow aldol reactions and lead to $\alpha,\beta$-unsaturated products. In this case, though, DABCO is a much better leaving group than the hydroxyl group, so enolization leads to loss of DABCO in an E1cB elimination, giving the product of the reaction. DABCO is recovered and is a catalyst.

A disadvantage of the Baylis–Hillman reaction is its rate: typically, several days’ reaction time are required. Pressure helps speed the reaction up, but as a catalyst DABCO is about the best. It is nucleophilic because of the ‘tied back’ alkyl groups, but importantly it is a good leaving group because it has a relatively low $pK_a$, meaning that it leaves easily in the last step. As you have seen before, good nucleophiles are usually bad leaving groups, although there are many exceptions. DABCO’s combination of nucleophilicity and leaving group ability is perfect here.
The exposed nature of the nitrogen atom in cyclic amines means that nitrogen heterocycles are very frequently encountered in drug molecules, particularly those operating on the central nervous system (cocaine, heroin, and morphine all contain nitrogen heterocycles, as do codeine and many tranquillizers, such as Valium). But the ring can also be used as a support for adding substituents that hinder the nitrogen’s lone pair. Just as the nitrogen atom of piperidine is permanently exposed, the nitrogen atom of 2,2,6,6-tetramethylpiperidine (TMP) nestles deep in a bed of methyl groups. The lithium salt of TMP (LiTMP) is an analogue of LDA—a base that experiences enormous steric hindrance that can be used in situations where the selectivity even of LDA fails.

Aziridine: ring strain promotes ring opening

Aziridine and azetidine are stable, if volatile, members of the saturated nitrogen heterocycle family, and aziridine has some interesting chemistry of its own. Like pyrrolidine and piperidine, aziridine can be acylated by treatment with an acyl chloride, but the product is not stable. The ring opens with attack of chloride, a relatively poor nucleophile, and an open-chain secondary amide results.

You can view this ring opening as very similar to the ring opening of an epoxide (Chapter 19)—in particular, a protonated epoxide, in which the oxygen bears a positive charge. The positive charge is very important for aziridine opening because, when the reaction is done in the presence of a base, removal of the proton leads immediately to the neutral acyl aziridine, which is stable.

The ring opening of aziridine is a useful way of making larger heterocycles: anything that puts a positive charge on nitrogen encourages the opening by making N a better leaving group, whether it’s protonation or, as shown below, alkylation. Alkylation of aziridine in base gives the N-substituted aziridine as you might expect, but a second alkylation leads to a positively charged aziridinium salt that opens immediately to a useful bromoamine.
We have just mentioned the protonation of aziridine, and you might imagine from what we said earlier about the comparative nucleophilicity and basicity of nitrogen heterocycles and their acyclic counterparts that aziridine will be even more nucleophilic than pyrrolidine, and about as basic. Well, it isn’t. The idea that ‘tying back’ the alkyl groups increases nucleophilicity is only valid for unstrained five or six-membered rings: with small rings another effect takes over.

Aziridine is, in fact, much less basic than pyrrolidine and piperidine: the $pK_a$ for its protonation is only 8.0. This is much closer to the $pK_a$ of a compound containing an $sp^2$ hybridized nitrogen atom—the imine in the margin, for example. This is because the nitrogen’s lone pair is in an orbital with much more s character than is typical for an amine, due to the three-membered ring. This is an effect we have discussed before, in Chapter 18, and you should re-read pp. 412–415 if you need to refresh your memory. There we compared three-membered rings with alkynes, explaining that both could be deprotonated relatively easily. The anion carries a negative charge in a low-energy orbital with much s character: the same type of orbital carries aziridine’s lone pair.

The s character of the aziridine nitrogen’s lone pair has other effects too. The lone pair interacts very poorly with an adjacent carbonyl group, so N-acyl aziridines such as the one you saw on p. 973 behave not at all like amides. The nitrogen atom is pyramidal and not planar, and the stretching frequency of the C=O bond (1706 cm$^{-1}$) is much closer to that of a ketone (1710 cm$^{-1}$) than that of an amide (1650 cm$^{-1}$).

The s character of the lone pair means that the nitrogen atom inverts very slowly, rather like a phosphine. Usually it is not possible for nitrogen to be a stereogenic centre because inversion is too rapid—the transition state for nitrogen inversions (in which the lone pair is in a p orbital) is low in energy. But with an aziridine, getting the lone pair into a p orbital requires much more activation energy, so nitrogen can be stereogenic. The two stereoisomers of the N-substituted aziridine in the margin can be separated and isolated.

### Oxygen heterocycles

Ring-opening chemistry is characteristic of oxygen heterocycles too, and there is no need for us to revisit epoxide opening here. Epoxides are particularly reactive because ring-opening releases ring strain, driving the reaction forward. In general, though, oxygen heterocycles, as cyclic ethers, are relatively unreactive: ethers are the least reactive of all the common functional groups. This is one of the main reasons why THF and dioxane are such important solvents. A second reason is that they solvate organometallics by donating a lone pair to stabilize an electron-deficient metal cation (Li, for example). Cyclic ethers are better donors (more nucleophilic) than acyclic ones for the same reason that cyclic amines are more nucleophilic than acyclic ones.

This interaction of the lone pair with a Lewis acid can be exploited to make ethers more reactive. BF$_3$ is commonly used to activate cyclic ethers towards nucleophilic attack, and even with epoxides it increases the rate and yield of the reaction when organometallic reagents are used as nucleophiles. BuLi does not react with oxetane unless a Lewis acid, such as BF$_3$, is added, when it opens the four-membered ring to give a quantitative yield of $n$-heptanol. Without ring strain to help the reaction along, THF, by contrast, gives only a low yield of the product even with a Lewis acid.
A more common (if often unwanted) reaction between BuLi and THF is not nucleophilic attack, but deprotonation. You will have noticed that reactions involving BuLi in THF are invariably carried out at temperatures of 0 °C or below—usually –78 °C. This is because, at temperatures above 0 °C, deprotonation of THF begins to take place. The deprotonated THF is unstable, and it undergoes a reaction we call a reverse [2 + 3] cycloaddition (see Chapter 34). Here is the mechanism (we have represented the organolithium as an anion to help with the arrows). The products are: (1) the (much less basic) enolate of acetaldehyde and (2) ethylene. The first tends to polymerize, and the second usually (but see the box below!) evaporates from the reaction mixture.

The case of the unexpected ethyl group

Some chemists in Belgium were studying the reactions of the organolithium shown here to find out whether the anionic centre would attack the double bond to form a five-membered ring. The reaction was slow, and they stirred the organolithium in THF for 6 hours at 0 °C. When they worked the reaction up they found no five-membered ring products: instead they got a compound with an extra ethyl group! They showed that this ethyl group, in fact, comes from THF: the organolithium did not add to the double bond in the same molecule, but it did add slowly and in low yield to the double bond of the ethylene that is formed by decomposition of THF.

The most common use of tetrahydropyran derivatives is as protecting groups: you met this in Chapter 23.

Sulfur heterocycles

As you saw in Chapter 27, sulfur stabilizes an adjacent anion, meaning that sulfur heterocycles are much easier to deprotonate than THF. The most important of these contains two sulfur atoms: dithiane. Deprotonation of dithiane occurs in between the two heteroatoms, and you saw some chemistry that arises from this on p. 661. The series of reactions below illustrates nicely both dithiane chemistry and the ring opening of oxygen heterocycles in the presence of BF₃. This substituted derivative of dithiane is deprotonated by BuLi to give a nucleophilic organolithium that will attack electrophiles—even oxygen heterocycles—provided BF₃ is present. The products are formed in excellent yield, even when the electrophile is THP, with no ring strain to drive the reaction. After the addition reaction the dithiane ring can be hydrolysed with mercury(II) to give a ketone carrying other useful functional groups.

THF stability

The half-life of n-BuLi in THF (in the presence of TMEDA) is 40 minutes at 20 °C, 5.5 hours at 0 °C, and 2 days at –20 °C. Diethyl ether is much less readily deprotonated: at 20 °C in ether n-BuLi has a half life of 10 hours. With more basic organolithiums, the rate of decomposition of THF is even faster, and t-BuLi can be used in THF only at –78 °C. At –20 °C t-BuLi has a half-life in THF of only 45 minutes; in ether its half-life at this temperature is 7.5 hours.
Conformation of saturated heterocycles

Using NMR to study conformation: the Karplus relationship

In Chapters 13 and 18 we explained that coupling in NMR spectra is a through-bond (and not a through-space) effect—that is why trans alkenes have bigger coupling constants than cis alkenes, and why axial–axial coupling in six-membered rings is larger than axial–equatorial or equatorial–equatorial coupling. We now need to build some more detail into your understanding of the relationship between conformation and coupling constants so we can use NMR to probe the conformations adopted by saturated rings.

The coupling constants in a cyclohexane tell us that coupling is greatest when the C–H bonds involved are most parallel—in other words when their dihedral angle is close to 180° or 0°. C–H bonds in simple cyclohexanes can have dihedral angles of only 60° or 180°, but by examining coupling constants in a range of other compounds, it is possible to draw up a description of the way coupling varies with dihedral angle. For example, in the bicyclic compound in the margin, the black protons have a dihedral angle close to 90° and the coupling constant is 0 Hz. The complete correlation was worked out by Karplus in the 1960s and is called the Karplus relationship. It is easiest to understand as a graph of $J$ against dihedral angle.

Examine the graph above carefully and note these principal features:

- Coupling is largest at 180° when the orbitals of the two C–H bonds are perfectly parallel (the situation in a trans alkene or the trans-diaxial C–H bonds of a cyclohexane).
- Coupling is nearly as large at 0° when the orbitals are in the same plane but not parallel (the situation in a cis alkene).
- Coupling is zero when the dihedral angle is 90°—orthogonal orbitals do not interact.
- The curve is flattened around 0°, 90°, and 180°—$J$ varies little in these regions from compound to compound.
- The curve slopes steeply at about 60° and 120°—$J$ varies a lot in this region with small changes of angle and from compound to compound.
- Numerical values of $J$ vary with substitution, ring size, etc., but the Karplus relationship still works—it gives good relative values.

The determination of conformation by NMR may determine configuration at the same time. This often occurs when there are two or more substituents on the ring. Here is a simple example: you saw in Chapter 16 that the reduction of 4-t-butylcyclohexanone can be controlled by choice of reagent to give either a cis or a trans alcohol.

---

Dihedral angles

The dihedral angle is obvious in a Newman projection—it is the angle between the two C–H bonds projected on a plane orthogonal to the C–C bond. In a Newman projection this plane is the plane of the paper, and here the angle is 180°.

Another way to think of the dihedral angle is by imagining the C–C bond lying along the spine of a partially opened book. If the C–H bonds are written one on one page and the other on the other, then the dihedral angle is the angle between the pages of the book.
The products are easy to tell apart because the green H appears quite different in the NMR spectrum in the two cases. In one it is quite a fine multiplet; in the other it is much broader.

The bulky t-butyl group always goes equatorial, and each OH group has two identical axial neighbours and two identical equatorial neighbours (two are shown in black in the scheme at the bottom of p. 796—there are two more at the front). Each coloured H appears as a triplet of triplets. In the cis alcohol both couplings are small (2.72 and 3.00 Hz) but in the trans alcohol the axial–axial coupling is much larger (11.1 Hz) than the axial–equatorial (4.3 Hz) coupling.

The same ideas can be used to study conformation in saturated heterocyclic systems. Hydrogenation of the double bond in this unsaturated acetal gives the saturated compound as a single isomer. But which one? Are the two substituents, Me and OEt, cis or trans?

The appearance of the two black hydrogens in the NMR spectrum reveals the answer and also shows what conformation the molecule adopts. There is a 1H signal at 3.95 ppm (which is therefore next to oxygen) and it is a double quartet. It must be the hydrogen next to the methyl group because of the quartet coupling. The quartet coupling constant has the ‘normal’
CHAPTER 31 SATURATED HETEROCYCLES AND STEREOELECTRONICS

\[ \delta_4 \text{H} 3.95, 1\text{H}, \text{dq}, J_9 \text{ and } 6.5 \text{ Hz} \]

\[ \delta_4 \text{H} 4.40, 1\text{H}, \text{dd}, J_9 \text{ and } 2 \text{ Hz} \]

\[ J \text{ value of } 6.5 \text{ Hz}. \text{ The doublet coupling is } 9 \text{ Hz and this is too large to be anything other than an axial–axial coupling. This hydrogen is axial.} \]

There is another 1H signal at 4.40 ppm (next to two oxygens), which is a doublet doublet with \( J = 9 \) and 2 Hz. This must also be an axial proton as it shows an axial–axial (9 Hz) and an axial–equatorial coupling. We now know the conformation of the molecule.

Both black hydrogens are axial so both substituents are equatorial. That also means in this case that they are \textit{cis}. But note that this is because they are both on the same, upper side of the ring, not because they are both equatorial! The hydrogen at the front has two neighbours—an axial (brown) H, \( J = 9 \), and an equatorial (green) H, \( J = 2 \) Hz. All this fits the Karplus relationship as expected. You may have spotted that the H at the back appears to be missing a small coupling to its equatorial neighbour. No doubt it does couple, but that small coupling is not noticed in the eight lines of the double quartet. Small couplings can easily be overlooked.

When this compound is allowed to stand in slightly acidic ethanol it turns into an isomer. This is the \textit{trans} compound and its NMR spectrum is again very helpful. The proton next to the methyl group is more or less the same but the proton in between the two oxygen atoms is quite different. It is at 5.29 ppm and is an unresolved signal of width about 5 Hz. In other words it has no large couplings and must be an equatorial proton. The conformation of the \textit{trans} compound is shown in the margin.

Because coupling constants in six-membered rings are well-defined, the formation of a heterocyclic ring can be used as a tool to determine stereochemistry. Suppose you have one diastereoisomer of a 1,3-diol and you want to find out which stereoisomer it is. You might think of using the NMR coupling constants of the two black protons. But that will do no good because the molecule has no fixed conformation. Free rotation about all the \( \sigma \) bonds means that the Karplus equation cannot be used and a time-averaged value of about 6–7 Hz will probably be observed for both protons regardless of stereochemistry.

Suppose now we make an acetal from the 1,3-diol with benzaldehyde. Acetal formation is under thermodynamic control, so the most stable possible conformation will result with the large phenyl group equatorial and the two R groups either both equatorial or one equatorial and one axial, depending on which diastereoisomer you started with.

\[ \text{This diastereoisomer} \quad \text{gives an acetal in this conformation} \]

\[ \text{this diastereoisomer} \quad \text{gives an acetal in this conformation} \]

Now the molecule has a fixed conformation and the coupling constants of the black Hs to the neighbouring CH\(_2\) group can be determined—an axial H will show one large \( J \) value, an equatorial H only small \( J \) values.

\[ \text{Deducing the stereochemistry of a new antibiotic} \]

Only fully saturated six-membered rings are really chairs or boats. Even with one double bond in the ring, the ring is partly flattened: here we will look at an even flatter example. A unique antibiotic has been discovered in China and called ‘\text{chuangxinmycin}’ (meaning ‘a new kind of mycin’ where mycin = antibiotic). It is unique because it is a sulfur-containing indole: few natural products and no other antibiotics have this sort of structure.

The structure itself was easy to elucidate, but the stereochemistry of the two black hydrogens was not so obvious. The coupling constant \( (J) \) was 3.5 Hz. During attempts to synthesize the compound, Kozikowski hydrogenated the alkene ester below to give an undoubted \textit{cis} product (hydrogenation is \textit{cis} selective: see Chapter 23, p. 535).

\[ \begin{align*}
\text{chuangxinmycin} & \quad \text{NaOH} \\
\text{Me}^+ & \quad \text{H}_2 \text{O} \\
\text{minor by-product: trans stereoisomer}
\end{align*} \]
The $3J$ coupling between the black hydrogens in this compound was 4.1 Hz, much the same as in the antibiotic and, when the ester group was hydrolysed in aqueous base, the main product was identical to natural chuangxinmycin. However, there was a minor product, which was the trans isomer. It had $3J = 6.0$ Hz. Note how much smaller this value is than the axial–axial couplings of 10 Hz or more in saturated six-membered rings. The flattening of the ring reduces the dihedral angle, reducing the size of $J$.

Coupling constants do not always give unambiguous information about stereochemistry, and in the next section we look at one technique which allows structural information to be extracted from NMR spectra without relying on coupling.

**Determining stereochemistry when coupling constants are no help: the nuclear Overhauser effect**

The coupling constant between the green protons of the compound below is rather large, at 11 Hz—about the same as the trans diaxial coupling in a cyclohexane. The Karplus relationship suggests the green protons must therefore spend much of their time with their bonds arranged with a dihedral angle close to 180°, and from this we can deduce that the compound has the conformation, as well as the configuration, shown. A more difficult problem is the assignment of the stereochemistry of the elimination product from this bromoamine and base. It's not a simple question, because the elimination also involves rearrangement of the amino group. The product is an alkene with two possible geometries.

Usually we would use coupling constants to determine alkene geometry, but they are no use here as there is only one proton on the alkene: it will be a singlet in both compounds. In such cases, we can make use of a quirk of NMR known as the **nuclear Overhauser effect** (NOE). NOE is rather different from coupling in the information it provides: it tells us which hydrogens are close in space rather than their relationship through bonds as revealed by coupling constants.

The details of the origin of the nuclear Overhauser effect are beyond the scope of this book, but we can give you a general idea of what the effect is. As you learned in Chapters 3 and 13, when a proton NMR spectrum is acquired, a pulse of radio frequency electromagnetic radiation jolts the spins of the protons in the molecule into a higher energy state. The signal we observe is generated by those spins dropping back to their original states. So far we have assumed that the drop back down is spontaneous, just like a rock falling off a cliff. In fact it isn’t—something needs to ‘help’ the protons to drop back again—a process called relaxation. And that ‘something’ is other nearby magnetically active nuclei—usually more protons. Notice nearby—nearby in space not through bonds. With protons, relaxation is always fast, and the number of nearby protons does not affect the appearance of the NMR spectrum.

Although in a normal spectrum peak intensity is independent of the number of nearby protons, by using methods whose description is beyond the scope of this book it is possible to modify the intensity of the peaks very slightly according to the number of protons that are nearby. The basis of the method is that certain protons (or groups of identical protons) are irradiated selectively (in other words, they are jolted into their high energy state and held there by a pulse of radiation at exactly the right frequency—not the broad pulse needed in a normal NMR experiment). Under the conditions of the experiment, this causes protons that were relying on those irradiated protons to relax them to appear as a slightly more intense (by maybe just a few per cent) peak in the NMR spectrum. This effect is known as the nuclear Overhauser effect, and the increase in intensity of the peak the nuclear Overhauser enhancement. Both are shortened to ‘NOE’.

**Why you can’t integrate $^{13}$C NMR spectra**

Relaxation is the real reason why you can’t integrate $^{13}$C signals. Relaxation of $^{13}$C is slow, but is fastest with lots of nearby protons. This is the reason that you will often find that $–\text{CH}_3$ groups show strong signals in the $^{13}$C NMR, while quaternary carbons, with no attached protons, show weak ones: quaternary carbons relax only slowly, so we don’t detect such an intense peak. Allowing plenty of time for all $^{13}$C atoms to relax between pulses gives more proportionally sized peaks, but at the expense of a very long NMR acquisition time.
All you need to be aware of at this stage is that irradiating protons in an NOE experiment gives rise to enhancements at other protons that are nearby in space—no coupling is required, and NOE is not a through-bond phenomenon. The effect also drops off very rapidly: the degree of enhancement is proportional to $1/r^6$ (where $r$ is the distance between the protons) so moving two protons twice as far apart decreases the enhancement one can give to the other by a factor of 64. NOE spectra are usually presented as differences: the enhanced spectrum minus the unenhanced, so that the small enhancements of intensity in the peaks of certain protons can be spotted immediately.

Applying NOE to the problem in hand solves the structure. If the protons next to the nitrogen atom in the piperidine ring are irradiated, the signal for the alkene proton increases in intensity, so these two groups of protons must be near in space. The compound is the $E$ alkene.

Data from NOE experiments nicely supplement information from coupling constants in the determination of three-dimensional stereochemistry too. Reduction of this bicyclic ketone with a bulky hydride reducing agent gives one diastereoisomer of the alcohol, but which? Irradiation of the proton next to the OH group leads to an NOE to the green proton. This suggests that the two protons are on the same side of the molecule and that reduction has occurred by hydride delivery to the face of the ketone opposite the two methyl groups on the three-membered ring.

A combination of coupling constants and NOE effects is routinely used to assign the stereochemistry of reaction products.

Heteroatoms in rings have axial and equatorial lone pairs

To a first approximation, the conformation of five- and six-membered saturated heterocycles follows very much the same principles as the conformation of carbocyclic compounds that we detailed in Chapter 16. For dithiane the conformation is as shown in the margin. Since the sulfur atoms have lone pairs, they too occupy axial and equatorial positions. The same is true of dioxane or of piperidine.

We have coloured the lone pairs green or black according to whether they are axial or equatorial, but you can also consider the colour coding in a different way: black lone pairs are parallel with C–C or C–heteroatom bonds in the ring; green lone pairs are parallel with axial C–H bonds outside the ring, or, if the ring has substituents, with the bonds to those substituents. This substituted tetrahydropyran illustrates all this. Notice that the equatorial substituents next to the heteroatom are parallel with neither the green nor the black lone pair.

Why is this important? There are many reactions in which lone pairs have an important role to play. For example, in an acetal hydrolysis, stabilization of the forming positive charge by an adjacent lone pair facilitates the elimination step of the mechanism. Let’s consider what happens in this acetal hydrolysis where the acetal is a saturated heterocycle. From Chapter 11, you expect this to be the mechanism:
Yet when we try to draw the conformation of the lone pairs we run into a problem: neither overlaps with the C–O bond that is breaking and so neither can donate its electron density into the C–O $\sigma^*$. Another way of looking at this is to say that the intermediate oxonium ion—with a C=O double bond formed by one of the oxygen’s lone pairs—would be extremely strained. Not surprisingly, the rate of hydrolysis of this acetal is very slow compared with similar ones in which overlap between the oxygen lone pair and the C–O $\sigma^*$ is possible. The acetal on the right hydrolyses about $10^{10}$ times faster.

You have just seen that overlap between orbitals governs NMR coupling constants; other situations where orbital overlap is important are:

- E2 elimination reactions (Chapter 17)
- reactions of cyclic molecules (Chapter 32)
- the Felkin–Anh transition state conformation (Chapter 33)
- fragmentations and rearrangements (Chapter 36).

Together, these effects are called stereoelectronic effects because they all depend on the orientation of orbitals.

Some substituents of saturated heterocycles prefer to be axial: the anomeric effect

Many of the stereoelectronic effects in the list above govern reactivity, but the next section will deal with how stereoelectronic effects affect structure—and in particular conformation. Some of the most important saturated oxygen heterocycles are the sugars. Glucose is a cyclic hemiacetal—a pentasubstituted tetrahydropyran if you like—whose major conformation in solution is shown below. About two-thirds of glucose in solution exists as this stereoisomer, but hemiacetal formation and cleavage is rapid, and this is in equilibrium with a further one-third that carries the hemiacetal hydroxyl group axial (<1% is in the open-chain form).

Having read Chapter 16 you will not be surprised that glucose prefers all its substituents to be equatorial. For four of them, of course, there is no choice: they are either all-equatorial or all-axial, and the only way they can get from one to the other is by ring-flipping. But for the fifth substituent, the hydroxyl group next to the ring oxygen (known as the anomeric hydroxyl group), a choice between axial or equatorial is made available by hemiacetal cleavage and re-formation—it can invert its configuration. What is perhaps surprising is that the equatorial preference of this hydroxyl group is so small—only 2.1. Even more surprising is that, for most derivatives of glucose, the anomeric substituents prefer to be axial rather than equatorial.
Move away from glucose and the effect is still there in other substituted tetrahydro-
pyrans. Listed below are the NMR signals of the chloro compound in the margin. There are
now only two possible conformations (no configurational changes are possible because
this is not a hemiacetal)—both shown—and from the NMR spectrum you should be able
to work out which one this compound has.

The key point is that axial–axial couplings are large (>8 Hz, say), even with adjacent electro-
negative atoms (which tend to lower coupling constants). So if H1 were an axial proton, you
would expect it to have a large coupling to H2. But it doesn’t—it couples to H2 with J of only
2.0 Hz. (The other coupling is a W-coupling to H3, also of 2.0 Hz: see p. 296.) Similarly, we
know that the 12.9 Hz coupling shared by the two H5 protons must be a geminal (J) coupling.
One of H5a or H5b must be axial, yet both couple to H4 with J < 4 Hz, so H4 cannot be axial.
With this evidence, we have to conclude that H1 and H4 (and therefore H2 and H3) are equa-
torial, so the compound must exist mainly in the all-axial conformation. (The 0.6 Hz cou-
pling to H5b is another W-coupling, and shows that H5b is the equatorial proton and H5a
therefore the axial one.) This axial preference is called the anomeric effect.

**The anomeric effect**

In general, any tetrahydropyran bearing an electronegative substituent in the 2-position will
prefer that substituent to be axial. This is known as the anomeric effect.

But why? This goes against all of what we said in Chapter 16 about axial substituents being
more hindered, making conformations carrying axial substituents disfavoured. The key again
is stereoelectronics, and we can now link up with the message we left you with at the end of the
last section: elimination reactions are possible only when the orbitals involved are parallel.

An amide is more stable (less reactive) than a ketone because the p orbital of the N and the
low-lying C=O π* of the carbonyl can lie parallel—they can overlap and electron density can
move from nitrogen into the C=O bond, weakening C=O. (Evidence for this comes from the
lower IR stretching frequency of an amide C=O, among other things.) But C–X bonds also
have low-lying antibonding orbitals—the C–X σ*—so we would expect a molecule likewise to
be stabilized if an adjacent heteroatom could donate electrons into this orbital. Take the
generalized tetrahydropyran in the box above, for example, with X=Cl, say. This molecule is
most stable if an oxygen lone pair can overlap with C–Cl σ*, as shown in the margin.

But it can do this only if the chlorine is axial! Remember what we pointed out earlier: the
oxygen’s equatorial lone pairs are parallel with nothing but bonds in the ring, so the oxygen’s
axial lone pair is the only one that can help stabilize the molecule, and it can only do this
when the Cl is axial. Only the axial conformation benefits from the stabilization, and this is
the origin of the anomeric effect.

How shall we represent the stabilization? Comparing again with the amide stabilization, you
might think about how to represent it with curly arrows: this is straightforward with the amide
and you have seen it many times. But it looks odd with our heterocycle: electron density moves
from O to Cl, and the C–Cl bond is weakened. If the process carried right on, Cl$^-$ would leave.

This is exactly what did happen in the acetal we presented you with as an example on p. 801: only the axial OAr could leave, however, because of the same requirement for overlap with an oxygen lone pair. In the real structure that we are now looking at, the Cl is still there: the C–Cl bond is weaker, and some of the oxygen’s electron density is delocalized on to Cl. This can be seen in crystal structures: compounds exhibiting an anomeric effect have a longer (and therefore weakened) bond outside the ring and a shorter, stronger C–O bond within the ring.

### The anomeric effect in spiroketals

Now that you know about the anomeric effect, you should add it to your mental array of possible ways to explain ‘unexpected’ results. Here is an example. Many fruit flies have pheromones based around a ‘spiroketal’ structure, which we could represent without stereochemistry as shown below. You can imagine the spiroketal (that is, an acetal of a ketone made of two rings joined at a single atom) being made from a dihydroxyketone—and, indeed, this is very often how they are made synthetically. But this is a bad representation because these compounds do have stereochemistry, and the stereochemistry is very interesting.

Let’s start with the simplest example, with R=H (a pheromone of the olive fly). Once you have drawn one ring in its chair conformation, there are three ways of attaching the other ring, shown here. If you think they all look the same, consider the orientation of each C–O bond with respect to the ring that it is not part of: you can have each C–O axial or equatorial, and there are three possible arrangements (three conformations).

Without knowing about the anomeric effect, you would find it hard to predict which conformation is favoured, and, indeed, you might expect to get a mixture of all three. But NMR tells us that this compound exists entirely in one conformation: the last one here, in which each oxygen is axial on the other ring. Only in this conformation can both C–O bonds benefit from an anomeric effect—this is often known as the double anomeric effect.

### Related effects in other types of compounds

The key requirement for the anomeric effect is that there is a heteroatom with a lone pair (O, N, S usually) adjacent to (that is, in a position to interact with) a low-lying antibonding orbital—usually a C–X $\sigma^*$ (where X=halogen or O). The C–X bond doesn’t have to be within the ring—for example, the nitrogen heterocycle on the left prefers to have the R group axial so that the nitrogen gets an equatorial lone pair. Equatorial lone pairs are parallel with bonds within the ring, one of which is C–O, and this conformation is therefore stabilized by an N lone pair/C–O $\sigma^*$ interaction.
It would be a bit much for the 1,3,5-triazine on the right to have all three t-butyl groups axial (too much steric hindrance), but it can get away with having one of them axial, benefitting from the resulting equatorial lone pair, which can overlap with two C–N σ* s in the ring.

It’s not only in six-membered rings that stereoelectronic interactions between filled and unfilled orbitals stabilize some conformations more than others. Steroelectronic effects control the conformations of many types of molecules.

- Any conformation in which a lone pair is anti-periplanar to a low-energy antibonding orbital will be stabilized by a stereoelectronic interaction.

We shall look at three common compounds that are stabilized by stereoelectronic effects: in two cases, the stabilization is specific to one conformation, and we can use stereoelectronics to explain what would otherwise be an unexpected result.

We start with a compound that is so simple that it has only one conformation because it has no rotatable bonds: dichloromethane. You may have wondered why it is that, while methyl chloride (chloromethane) is a reactive electrophile that takes part readily in substitution reactions, dichloromethane is so unreactive that it can be used as a solvent in which substitution reactions of other alkyl halides take place. You may think that this is a steric effect: indeed, Cl is bigger than H. But CH₂Cl₂ is much less reactive as an electrophile than ethyl chloride or propyl chloride: there must be more to its unreactivity. And there is: dichloromethane benefits from a sort of ‘permanent anemic effect’. One lone pair of each chlorine is always anti-periplanar to the other C–Cl bond so that there is always stabilization from this effect.

Among the most widespread classes of acyclic compounds to exhibit stereoelectronic control over conformation are acetals. Take the simple acetal of formaldehyde and methanol, for example: what is its conformation? An obvious suggestion is to draw it fully extended so that every group is fully antiperiplanar to every other—this would be the lowest energy conformation of pentane, which you get if you just replace the Os with CH₂s.

The trouble is, in this conformation none of the oxygen lone pairs get the chance to donate into the C–O σ* orbitals. Although putting the bonds anti-periplanar to one another makes steric sense, electronically, the molecule much prefers to put the lone pairs anti-periplanar to the C–O bonds, so the bonds themselves end up gauche (synclinal) to one another. This is known as the gauche effect, but is really just another way in which the stereoelectronic effects that give rise to the anomeric effect turn up in acyclic systems.

Finally, an even more familiar example that you may never have thought about. You are well aware now that amides are planar, with partially double C–N bonds, and that tertiary amides have one alkyl group cis to oxygen and one trans. But what about esters? Esters are less reactive than acyl chlorides because of donation from the oxygen p orbital into the carbonyl π*, so we expect them to be planar too, and they are. But there are two possible planar conformations for an ester: one with R cis to oxygen and one with R trans. Which is preferred?
Here are the two conformations drawn out for ethyl acetate. When the ethyl group (= R) and O are cis, not only can one oxygen lone pair interact with the C=O π*, but the other lone pair can also donate into the π* of the C=O bond. This is not possible when Et and O are trans: they are no longer anti-periplanar. The cis conformation of esters is generally the preferred one, even in formate esters, where the alkyl group ends up in what is clearly a more sterically hindered orientation.

Cyclic esters—lactones—cannot lie cis because of the ring, and this is one of the reasons why lactones are distinctly more reactive than esters and in many reactions behave more like ketones: lactones are quite easy to reduce with NaBH₄, for example.

Making heterocycles: ring-closing reactions

We have talked about the structure of saturated heterocycles, particularly with regard to stereoelectronic control over conformation, and before that we looked at some of their reactions. We will now look at how to make them. By far the most important way of making them is by ring-closing reactions because we can usually use the heteroatom as the nucleophile in an intramolecular substitution or addition reaction. Ring-closing reactions are, of course, just the opposite of the ring-opening reactions we talked about earlier in the chapter, and we can start with a reaction that works well in both directions: ring closure to form an epoxide. You know well that epoxides can be formed using m-CPBA and an alkene, but you have already seen examples where they form by an intramolecular substitution reaction such as this.

The same method can also be used to generate larger cyclic ethers. Oxetane, for example, is conveniently made by adding 3-chloropropyl acetate to hot potassium hydroxide. The first step in this reaction is the hydrolysis of the ester. The alkoxide produced then undergoes an intramolecular substitution reaction to yield oxetane.

Tetrahydropyran was prepared as early as 1890 by a ring closure that occurs when a mixture of 1,5-pentanediol with sulfuric acid is heated.

These are all S₂2 reactions, so you will not be surprised that nitrogen heterocycles can be prepared in the same way. Aziridine itself, for example, was first prepared in 1888 from 2-chloroethylamine. Related reactions can be used to form three-, five-, and six-membered nitrogen heterocycles, but fail to form four-membered rings. In fact, four-membered rings are generally among the hardest of all to form.
To illustrate this, the green columns of the table below show the rates (relative to six-membered ring formation = 1) at which bromoamines of various chain lengths cyclize to saturated nitrogen heterocycles of three to seven members.

aRelative to six-membered ring formation; bE = CO2Et

At first sight it may seem that these rates have been produced by a random number generator! There seems to be no rhyme or reason to them, and no consistent trend. To convince you that these numbers mean something, the table also shows, in the orange columns, the relative rates for another ring-closing reaction, this time forming four- to seven-membered rings that are not even heterocycles by intramolecular alkylation of a substituted malonate. Although the numbers are quite different in the two cases, the ups and downs are the same, and the final column summarizes the relative rates. Put another way, a rough guide (only rough—it doesn’t work in all cases) to the rate of ring formation is this.

**Rough guide to the rate of formation of saturated rings**

Fastest 5 > 6 > 3 > 7 > 4 > 8–10 slowest

We show the numbers in colour to highlight the fact that this seemingly illogical ordering of numbers actually conceals two superimposed trends. Once you get to five-membered rings, the rate of formation drops consistently as the ring size moves from ‘normal’ (5 and 6) to ‘medium’ (8 to 13) sized rings. ‘Small’ (3 and 4) rings insert into the sequence after 6.

The reason for the two superimposed trends is two opposing factors. Firstly, small rings form slowly because forming them introduces ring strain. This ring strain is there even at the transition state, raising its energy and slowing down the reaction. The activation energy for forming
a three-membered ring is very high, due to strain, but decreases as the ring gets larger. This explains why three- and four-membered rings don’t fit straightforwardly into the sequence.

But if the reaction rate simply depended on the strain of the product, the slowest reaction would be the formation of the three-membered ring, and six-membered rings (which are essentially strain-free) would form fastest. Yet the data shows that four-membered rings form more slowly than three-membered ones, and five-membered ones faster than six-membered ones. To explain this, we need to remind you of an equation we presented in Chapter 12.

\[ \Delta G^\ddagger = \Delta H^\ddagger - T \Delta S^\ddagger \]

The activation energy barriers \( \Delta G^\ddagger \) of our reactions are made up of two parts: an enthalpy of activation \( \Delta H^\ddagger \), which tells us about the energy required to bring atoms together against the strain and repulsive forces they usually have, and an entropy of activation \( \Delta S^\ddagger \), which tells us about how easy it is to form an ordered transition state from a wriggling and randomly rotating molecule.

\( \Delta G^\ddagger \) for three- and four-membered ring formation is large because \( \Delta H^\ddagger \) is large: energy is needed to bend the molecule into the strained small-ring conformation. \( \Delta H^\ddagger \) for five-, six-, and seven-membered rings is smaller: this is the quantifiable representation of the ‘ring strain’ factor we have just introduced. The second factor is one that depends on \( \Delta S^\ddagger \): how much order must be imposed on the molecule to get it to react. Think of it this way: a long chain has a lot of disorder, and to get its ends to meet up and react means it has to give up a lot of freedom. So, for the formation of medium and large rings, \( \Delta S^\ddagger \) is large and negative, contributing to a large \( \Delta G^\ddagger \) and slow reactions. For three-membered rings, on the other hand, the reacting atoms are already very close together and almost no order needs to be imposed on the molecule to get it to cyclize: rotation about just one bond is all that is needed to ensure that the amine group is in the perfect position to attack the \( \sigma^* \) of the C–Br bond in our example above. \( \Delta S^\ddagger \) is very small for three-membered rings so, while \( \Delta H^\ddagger \) is large, there is little additional contribution from the \( T \Delta S^\ddagger \) term and cyclization is relatively fast. Four-membered rings suffer the worst of both worlds: forming a four-membered ring introduces ring strain (\( \Delta H^\ddagger \)) and requires order (\( \Delta S^\ddagger \)) to be imposed on the molecule. They form very slowly as a result.

These results are summarized in the following box.

**Ring formation**

- Three-membered ring formation is fast—the product is strained so \( \Delta H^\ddagger \) is large but this is offset by the reacting atoms being as close as they can get in a freely rotating chain.
- Four-membered rings form slowly—the product is still significantly strained but the reacting atoms are now not right next to each other to offset this.
- Five-membered ring formation is often fastest of all. Significantly less strain and the ends are still not too far apart.
- Six-membered ring formation experiences no strain but neither does it have the advantage of the ends being close.
- Seven-membered rings and beyond form more slowly as \( \Delta S^\ddagger \) increases.
Thermodynamic control over ring size

In this section we have discussed the rate at which rings form: in other words the kinetics of ring formation. However, there are many ring-forming reactions that are under thermodynamic and not kinetic control. For example, you have already seen that glucose exists predominantly as a six-membered ring in solution. It could also exist as a five-membered ring: it doesn’t because although five-membered rings form faster than six-membered ones, they are usually less stable (remember, a six-membered ring is essentially strain-free). For similar thermodynamic reasons, it doesn’t exist as a seven-membered ring, even though you can draw a reasonable structure for it.

Thermodynamic control is important in other ways in carbohydrate chemistry because control over ring size allows selective protection of the hydroxyl groups of sugars. Compare these two reactions. Both of them give acetals from the same starting material, mannitol.

Don’t be put off by the way in which we have had to twist half the molecule round to draw the left-hand structure: the stereochemistry hasn’t changed. The important thing is that acetone reacts with mannitol to form three five-membered acetals (dioxolanes) while benzaldehyde forms only two six-membered acetals. This is quite a common result: when there is a choice, acetone prefers to react across a 1,2-diol to give a five-membered acetal, while aldehydes prefer to react across a 1,3-diol to form a six-membered acetal. Drawing a conformational diagram of the product on the right helps to explain why. All of the substituents are equatorial, making this a particularly stable structure. Now imagine what would happen if acetone formed this type of six-membered ring acetal. There would always be an axial methyl group, and the six-membered rings would be less stable.

Combatting ΔS‡—the Thorpe–Ingold effect

The rate of ring formation is affected not just by ring size but by substituents on the ring being formed. Compare the following relative rates ($k_{rel}$) for epoxide-forming cyclization reactions. The second looks as though it suffers more steric hindrance but nonetheless it is tens of thousands of times faster!

Adding substituents to other ring-forming reactions makes them go faster too: in the next two examples the products are oxetanes and pyrrolidines.
This effect is quite general, and is known as the Thorpe–Ingold effect after the first chemists to note its existence, in 1915.

> The Thorpe–Ingold effect

The Thorpe–Ingold effect is the way in which substituents on the ring increase the rate, or equilibrium constant, for ring-forming reactions.

As the box says, it’s not only rate that can be affected by additional substitution. Here are the relative equilibrium constants for the formation of an anhydride from a 1,4-dicarboxylic acid (the unsubstituted acid is called succinic acid, and the values are scaled so that $K_{rel}$ for the formation of succinic anhydride is 1). More substituents mean more cyclized product at equilibrium. The Thorpe–Ingold effect is both a kinetic and a thermodynamic phenomenon.

Now we need to explain why this is. The explanation comes in two parts, one of which may be more important than the other, depending on the ring being formed. The first part is more applicable to the formation of small rings, such as the first example we gave you.

If you measure the bond angles of chains of carbon atoms, you expect them to be close to the tetrahedral angle, 109.5°. The crystal structure of the 1,3-dicarboxylic acid in the margin, for example, shows a C–C–C bond angle of 110°. Now imagine adding substituents to the chain. They will repel the carbon atoms already there, and force them a little closer than they were, making the bond angle slightly less. X-ray crystallography tells us that adding two methyl groups to our 1,3-dicarboxylic acid decreases the bond angle by about 4°.

We can assume that the same is true in the alcohol starting materials for the epoxide-forming reactions on p. 808 (we can’t measure the angle directly because the compounds aren’t crystalline). Now consider what happens when both of these alcohols form an epoxide. The bond angle has to become about 60°, which involves about 50° of strain for the first diacid, but only 46° for the second. By distorting the starting material, the methyl groups have made it slightly easier to form a ring.

This part of the argument works only for small rings. For larger rings, we need another explanation, and it involves entropy. We’ll use the pyrrolidine-forming reaction as an example. We have explained the effect of $\Delta S^\circ$ (entropy of activation) on the rate of ring formation: as larger rings form they have to lose more entropy at the transition state, and this contributes to a less favourable $\Delta G^\circ$.
But, when the starting material has more substituents, it starts off with less entropy anyway. More substituents mean that some conformations are no longer accessible to the starting material—the green arcs on the structures on the right above show how the methyl groups hinder rotation of the N and CH₂Br substituents into that region of space. Of those fewer conformations, many approximate to the conformation in the transition state, and moving from starting material to transition state involves a smaller loss of entropy: ΔS‡ is less negative so ΔG‡ (= ΔH‡ – TΔS‡) is more negative and the ring forms faster. The same arguments apply to ΔS for the reaction as a whole (the difference in entropy between starting material and products), so increased substitution favours ring closure even under thermodynamic control.

Baldwin’s rules

Nearly all of the cyclization reactions that we have discussed have been intramolecular S₉2 reactions where one end of the molecule acted as the nucleophile displacing the leaving group on the other end. We kept to this sort of reaction in order to make valid comparisons between different ring sizes. But you can imagine making saturated heterocycles in plenty of other ways—intramolecular substitution at a carbonyl group, for example, such as happens in this lactonization reaction, or intramolecular addition of an oxyanion on to an alkyne.

Cyclization reactions can be classified by a simple system involving: (1) the ring size being formed, (2) whether the bond that breaks as the ring forms is inside (endo) or outside (exo) the new ring, and (3) whether the electrophile is an sp (digonal), sp² (trigonal), or sp³ (tetrahedral) atom. This system places three of the cyclizations just shown in the following classes.

1. The ring being formed has three members; the breaking C–Br bond is outside the new ring (exo); the C carrying Br is a tetrahedral (sp³) atom (tet).

2. The ring being formed has five members; the breaking C=O bond is outside the new ring (exo); the C being attacked is a trigonal (sp²) atom (trig).

3. The ring being formed has six members; the breaking C≡C bond is inside the new ring (endo); the C being attacked is a digonal (sp) atom (dig).

The classes of cyclization reactions are important, not because we have a compulsive Victorian desire to classify everything, but because which class a reaction falls into determines whether or not it is likely to work. Not all cyclizations are successful, even though they may look fine on paper! The guidelines that describe which reactions will work are known as Baldwin’s rules: empirical observations backed up by some sound stereoelectronic reasoning. Reactions can be classified according to these rules as ‘favoured’ and ‘disfavoured’. We will deal with the rules step by step and then summarize them in a table at the end.

Firstly, and not surprisingly (because we have been talking about them for much of this chapter):

- all exo-tet cyclizations are favoured

and, similarly (again you can find many examples in this book):

- all exo-trig cyclizations are favoured
Despite the variation in rate we have described for this type of reaction, *exo-tet* cyclizations have no stereoelectronic problems: the lone pair and the C–X σ* (X is the leaving group) can overlap successfully irrespective of ring size. The ring closures in the table on p. 809 all fall into this category. The same is true for *exo-trig* reactions: it is easy for the nucleophilic lone pair to overlap with the C=X π* to form a new bond. Examples include lactone formation such as the one on p. 810.

*Endo-tet* reactions are rather different. For a start:

- **5 and 6-endo-tet are disfavoured.**

*Endo-tet* reactions would not actually make a ring, but they fall conveniently into the system and we will look at them here. Here is a reaction that looks as though it contradicts what we have just said. The arrows in the reasonable-looking mechanism on the right describe a 6-endo-tet process because the breaking Me–O bond is within the six-membered ring transition state (even if no ring is formed).

![6-endo-tet reaction](image)

But Eschenmoser showed that, for all its appeal (intramolecular reactions usually outpace all alternatives), this mechanism is wrong. He mixed together the starting material for the reaction above with the hexadeuterated compound shown below, and re-ran the reaction. If the reaction had been intramolecular, the products would have contained either no deuterium, or six deuteriums. In the event, the product mixture contained about 25% of each of these compounds, with a further 50% containing three deuteriums. The products cannot have been formed intramolecularly, and this distribution is exactly what would be expected from an intermolecular reaction.

![Intermolecular reaction](image)

With *endo-trig* reactions, whether they work or not depends on the ring size.

- **3-, 4-, and 5-endo-trig are disfavoured; 6 and 7-endo-trig are favoured.**

The most important case in the *endo-trig* class is the disfavoured 5-endo-trig reaction and, if there is one message you take away from this section, it should be that 5-endo-trig reactions are disfavoured. The reason we say this is that 5-endo-trig cyclizations are reactions that look perfectly fine on paper, and at first sight it seems quite surprising that they won’t work. This intramolecular conjugate addition, for example, appears to be a reasonable way of making a substituted pyrrolidine.
But this reaction doesn’t happen: instead, the amine attacks the carbonyl group in a (favoured) 5-exo-trig cyclization.

Why is 5-endo-trig so bad? The problem is that the nitrogen’s lone pair has problems reaching round to the π* orbital of the Michael acceptor. There is no problem reaching as far as the electrophilic carbon in the plane of the substituents but, if it bends out of this plane, which it must if it is to overlap with the π* orbitals, it moves too far away from the methylene carbon to react. It’s like a dog chained just out of reach of a bone.

Lengthen the chain, though, and the dog gets his dinner. Here’s a perfectly straightforward 6-endo-trig, for which orbital overlap presents no problem.

Exceptions to Baldwin’s rules

Baldwin’s rules are only guidelines and, when a reaction is thermodynamically very favourable (Baldwin’s rules, of course, describe the kinetic favourability of a reaction) and there is no other possible pathway, 5-endo-trig reactions can take place. The most striking example is one that you met quite early on in this book (Chapter 11): the formation of a cyclic acetal (dioxolane) from a carbonyl compound and ethylene glycol. We don’t need to give again the full mechanism here, but you should check that you can still write it. The key step with regard to Baldwin’s rules is shown with a green arrow. It’s a 5-endo-trig reaction but it works!

In fact, cations frequently disobey Baldwin’s rules. Other well-defined exceptions to Baldwin’s rules include pericyclic reactions (Chapters 34 and 35) and reactions in which second-row atoms such as sulfur are included in the ring.

This 5-endo-trig reaction, the sulfur analogue of the amine cyclization that didn’t work, is fine. C–S bonds are long, and the empty 3d orbitals of sulfur may play a role by providing an initial interaction with the C–C π orbital.

With tet and trig cyclizations, exo is better than endo; with dig cyclizations, the reverse is true.

● All endo-dig cyclizations are favoured.
Move from 5-endo-trig to 5-endo-dig, and the reactions become much easier: even 4-endo-dig reactions work. Here is an example of 5-endo-dig.

We warned you to look out for 5-endo-trig reactions because they are disfavoured even though on paper they look fine. Now the alert is the other way round! We expect you’d agree that these endo-dig reactions look awful on paper: the linear alkyne seems to put the electrophilic carbon well out of reach of the nucleophile, even further away than in the 5-endo-trig reaction. The important thing with endo-dig cyclizations, though, is that the alkyne has two π* orbitals, one of which must always lie in the plane of the new ring, making it much easier for the nucleophile to get at.

● 3 and 4-exo-dig are disfavoured; 5 to 7-exo-dig are favoured.

These reactions are less important and we will not discuss them in detail.

**Baldwin’s rules and ring opening**

Baldwin’s rules work because they are based on whether or not orbital overlap can be readily achieved in the conformation required at the transition state. But the transition state is the same whether the reaction is going forwards or backwards—the principle of microscopic reversibility (which is discussed further in Chapter 39) says that, if a reaction goes via a certain mechanism, the reverse reaction must follow exactly the same path in the opposite direction. So Baldwin’s rules also apply to ring-opening reactions. This is where the unfavourability of 5-endo-trig really is important: this tetrahydrofuranyl ester, for example, looks set up to do an E1cB elimination in base. Indeed, when it is treated with methoxide in deuterated methanol it exchanges the proton α to the ester for deuterium, proving that the enolate forms. But it does not eliminate: elimination would be a reverse 5-endo-trig process and is disfavoured.

Whenever you think about a ring-opening reaction, consider its reverse, and assess whether it is favoured according to Baldwin’s rules.

Baldwin’s rules can be summarized in a chart. You should note the general outline of this chart: commit to memory that, broadly speaking, endo-tet and endo-trig are disfavoured; exo-tet and exo-trig are favoured, and the reverse for dig. Then you just need to learn the cut-off points that indicate the exceptions to this broad-brush view: 6-endo-trig falls into the favoured category while 4-exo-dig falls into the disfavoured one. And, if you really can remember only one thing, it should be that 5-endo-trig is disfavoured!
On p. 796 we considered the effect of changes in the dihedral angle on coupling constants. But the dihedral angle is not the only angle worth measuring: we should also consider how the two C–H bonds are spread out in space. The dihedral angle is what we see when we look down the spine of the book in our earlier analogy—now we want to look at the pages in the normal way, at right angles to the spine, as if we were going to read the book. We can show what we mean by fixing the dihedral angle at $0^\circ$ (the C–H bonds are in the same plane) and looking at the variation of $J$ with the ring size of some simple cyclic alkenes.

The wider apart the hydrogens are spread, the smaller the coupling constant. Remember, the dihedral angle stays the same ($0^\circ$)—we are just varying the angle in the plane. A dramatic illustration of this comes with the product of dehydrogenation of the natural product guaiol with elemental sulfur. From the brown, smelly reaction mixture, guaiazulene, a deep blue oil, can be distilled.

Some assignments are clear. The 6H doublet and the 1H septuplet are the isopropyl group, and the two 3H singlets belong to the two methyl groups—we can’t really say which belongs to which. The 1H singlet must be the green hydrogen as it has no neighbours and that leaves us with two coupled pairs of protons. One pair has $J = 4$ Hz and the other $J = 11$ Hz. From the values above, we expect to find larger coupling where the H–C–C–H angle is smaller, so we can say that the 4 Hz coupling is between the pair on the five-membered ring and the 11 Hz coupling is between the pair on the seven-membered ring.

When protons on a double bond in a ring have neighbours on saturated carbon, the coupling constants are all small and for the same reason—the angles in the plane of the ring are approaching $90^\circ$ even though the dihedral angles are $45–60^\circ$ in the examples on the left. A bizarre result of this is that the $J$ coupling between the red and black hydrogens is often about
the same as the allylic \((\delta\beta)\) coupling between the red and the green hydrogens. An example follows in a moment.

The ‘spreading out’ effect also affects vicinal \((\delta\alpha)\) couplings in simple saturated rings. No other ring size has so well defined a conformation as that of the six-membered ring, but we can still note useful trends as we move from 6 to 5 to 4 to 3. Briefly, in five-membered rings, cis and trans couplings are about the same. In four- and three-membered rings, cis couplings are larger than trans. But in all cases the absolute values of \(J\) go down as the ring gets smaller and the C–H bonds are ‘spread out’ more. Indeed, you can say that all coupling constants are smaller in small rings, as we shall see. But we need to examine a few examples in a bit more detail.

**Three-membered rings**

Three-membered rings have to be flat with all bonds eclipsed so the dihedral angle is \(0^\circ\) for cis Hs and \(109^\circ\) for trans Hs. Looking at the Karplus curve on p. 796, we expect the cis coupling to be larger, and it is. A good example is chrysanthemic acid, which is part of the pyrethrin group of insecticides found in the pyrethrum plant. Both cis and trans chrysanthemic acids are important, and in both isomers the coupling between the green proton on the ring and its brown neighbour on the double bond is 8 Hz. In the cis compound, the green proton is a triplet so the cis coupling in the ring is also 8 Hz. In the trans compound it is a double doublet with the second coupling, trans across the ring to the black H, of 5 Hz.

The most important three-membered rings are the epoxides. You saw in Chapter 13 (p. 295) that electronegative atoms reduce coupling constants by withdrawing electron density from the bonds that transmit the coupling ‘information’. This means that epoxide couplings are very small—much smaller than those of their closely related alkenes, for example. Compare the four coupling constants in the diagram: for the epoxide, all couplings are small, but cis coupling is larger than trans coupling. In alkenes, trans coupling is larger (Chapter 13, p. 293). The table summarizes the coupling constants for alkenes, epoxides, and cyclopropanes.

**Cerulenin**

The natural product cerulenin is an antibiotic containing a cis epoxide. The coupling constant between the black hydrogens is 5.5 Hz. The compound has been made from an unsaturated lactone by epoxidation and ring opening. Follow what happens to the coupling constant between the black hydrogens as this sequence develops.

The cis coupling in the alkene is small because it is in a five-membered ring. It gets smaller in the bicyclic epoxide because the black Hs are now in both five- and three-membered rings and both are next to oxygen, but it gets larger in cerulenin itself because the five-membered ring has been opened.
Four-membered rings

A similar situation exists with four-membered rings—the cis coupling is larger than the trans but they are generally both smaller than those in larger rings. A good example is the amino acid in the margin, the skeleton of the penicillins. The NMR spectrum contains three 1H signals in the middle regions. There is a singlet at δH 4.15 ppm that clearly belongs to the isolated green proton and two doublets at δH 4.55 and 5.40 ppm that must belong to the black protons. The coupling constant between them is 5 Hz and they are cis-related.

There are now large numbers of β-lactam antibiotics known and one family has the opposite (trans) stereochemistry around the four-membered ring. The typical member is thienamycin. We will analyse the spectrum in a moment, but first look at the differences—apart from stereochemistry—between this structure and the last. The sulfur atom is now outside the five-membered ring, the acid group is on a double bond in the same ring, and the amino group has gone from the β-lactam to be replaced by a hydroxyalkyl side chain.

Turning to the spectrum and the key question of stereochemistry, this is what the Merck discoverers said in their original article: "1H NMR spectra of thienamycin (and derivatives). . . show small vicinal coupling constants J ≤ 3 Hz for the two β-lactam hydrogens. Past experience with penicillins. . . shows the cis relationship of the β-lactam hydrogens to be always associated with the larger coupling." As we have just seen penicillins have J ~ 5 Hz for these hydrogens.

The NMR spectrum of a thienamycin derivative with protecting groups on the amine and carboxylic acids is shown below. Try your hand at interpreting it before you read the explanation. Your aim is to find the coupling constant across the four-membered ring.

*aSee p. 297 for discussion of AB systems.

The simple answer is 2.5 Hz. The signals at 3.15 and 4.19 ppm are the protons on the β-lactam ring and the 9 Hz extra coupling is to the CH2 in the five-membered ring. If you went into this spectrum in detail you may have been worried about the 12.5 and especially the 18 Hz couplings. These are J (geminal) couplings and we will discuss them in the next section. The full assignment is shown below.
We should emphasize that a coupling constant of 5 or 2.5 Hz in isolation would not allow us to assign stereochemistry across the four-membered ring but, when we have both, we can say with confidence that the larger coupling is between cis Hs and the smaller coupling between trans Hs.

**Five-membered rings**

You can visualize the conformation of a five-membered ring simply as a chair cyclohexane with one of the atoms deleted. But this picture is simplistic because the five-membered ring flexes (rather than flips) and any of the carbon atoms can be the one out of the plane. All the hydrogen atoms are changing positions rapidly and the NMR spectrum 'sees' a time-averaged result. Commonly, both cis and trans couplings are about 8–9 Hz in this ring size.

The best illustration of the similarity of cis and trans couplings in five-membered rings is a structure that was incorrectly deduced for that very reason. Canadensolide is an antifungal compound found in a *Penicillium* mould. The gross structure was quite easy to deduce from the mass spectrum, which gave the formula C_{11}H_{14}O_{4} by exact mass determination, the infrared, which showed (at 1780 and 1667 cm\(^{-1}\)) a conjugated five-ring lactone, and some aspects of the proton NMR. The proposed structure is shown in the margin.

The stereochemistry of the ring junction Hs (shown in black and green) is not in question. They are certain to be cis as it is virtually impossible for two five-membered rings to be fused trans. The stereochemical uncertainty involves the third stereogenic centre on the left-hand ring. The coupling constant between the black and green Hs is 6.8 Hz, while that between the green and brown Hs is 4.5. Is this different enough for them to be trans? The original investigators decided that it was.

The mistake emerged when some Japanese chemists made this compound by an unambiguous route. The NMR spectrum was quite like that of canadensolide, but not the same. In particular, the coupling between the green and brown Hs was 1.5 Hz—quite different! So they also made the other possible diastereoisomer and found that it was identical to natural canadensolide. The details are in the margin.

**An example of vicinal coupling in structural analysis: aflatoxins**

We can bring together a lot of these points in the structure of one compound, the dreaded aflatoxin. Aflatoxins were mentioned in Chapter 19: they occur in moulds, including those that grow on some foods, and cause liver cancer. These slow-acting poisons are among the most toxic compounds known. Aflatoxin B\(_1\) is an example. The four red protons on saturated carbons in the five-membered ring in the margin appear as two triplets: \(\delta_H 2.61\) (2H, t, \(J 5\) Hz) and \(\delta_H 3.42\) (2H, t, \(J 5\) Hz). The cis and trans couplings are the same. The yellow proton, on the junction between the two five-membered cyclic ethers, is a doublet \(\delta_H 6.89\) (1H, d, \(J 7\) Hz).

This is, of course, the cis coupling to the black hydrogen. The black hydrogen has this coupling too, but it appears as a doublet of triplets with a triplet coupling of 2.5 Hz: \(\delta_H 4.81\) (1H, dt, \(J 7\), 2.5, 2.5 Hz). These small couplings can only be to the two green hydrogens: the \(^3J\) and \(^4J\) couplings are indeed the same.

Finally there is another strange coincidence—each green hydrogen appears as a triplet with 2.5 Hz couplings. Evidently, the cis coupling across the double bond is also 2.5 Hz. We expect cis coupling in a cyclopentene to be small (it was 4 Hz in the azulene on p. 814), but not that small—it must be the electronegative oxygen atom that is reducing the value still further.

**Geminal (\(^2J\)) coupling**

For coupling to be seen, the two hydrogen atoms in question must have different chemical shifts—identical protons do not couple. For \(^2J\), or geminal, couplings the two hydrogen atoms are on the same carbon atom, so in order to discuss geminal coupling we must first consider what leads the two hydrogens of a CH\(_2\) group to have different shifts.

To introduce the topic, an example. It may seem to you that any six-membered ring might show different chemical shifts for axial and equatorial groups. But this doesn’t happen. Consider the result of this Robinson annelation reaction.
The two methyl groups at C4 give rise to a single signal in the $^{13}$C NMR at 27.46 ppm. Even though one of them is (pseudo)axial and one (pseudo)equatorial, the molecule exists in solution as a rapidly equilibrating mixture of two conformations. The axial green methyl in the left-hand conformer becomes equatorial in the right-hand conformer, and vice versa for the black methyl group. The equilibrium position must be 50:50 and fast exchange averages the chemical shifts of the two methyl groups. The same is true for the CH$_2$ groups around the back of the ring, which each appear as a triplet.

However, the enone is not the only product of this reaction. A methanol adduct is also formed by Michael addition of methanol to the conjugated enone. This product has two methyl signals at 26.1 and 34.7 ppm. If we examine the molecule by conformational analysis as we did for the first product we see a similar situation.

Similar but not the same. This time, the two conformations are not identical. One has the OMe group equatorial and the other has it axial. Even the two methyl groups do not entirely change places in the two conformations. True, the green methyl is axial on the left and equatorial on the right, but it has a gauche (dihedral angle 60°) relationship with the OMe group in both conformations. The black Me group is gauche to OMe on the left but anti-periplanar to the OMe group on the right. Averaging the two different conformations, in each of which the black and green methyl groups are different (that is, they don't just change places), does not lead to equalization of the two methyl groups.

Perhaps a simpler way to discover this is to use a configurational, rather than a conformational, diagram. The green methyl group is on the same face of the molecule as the MeO group, while the black methyl group is on the other face. No amount of ring flipping can make them the same. They are diastereotopic, a term we shall define shortly. And so are all three CH$_2$ groups in the ring. The green Hs are on the same face of the molecule as the MeO group while the black Hs are on the other face.

A proton NMR example confirms this, and here is one from an odd source. There are fungi that live on animal dung, called coprophilous fungi. They produce antifungal compounds, presumably to fight off competition! Anyway, in 1995 two new antifungal compounds were discovered in a fungus living on lemming dung. They were named coniochaetones A and B and their structures were deduced with the usual array of mass and NMR spectra. The proton spectra, run on a 600 MHz machine, are shown below, and they reveal considerable detail.

Some of the spectrum is essentially the same for the two compounds, but other parts are quite different. Coniochaetone A has a very simple spectrum, very easily assigned. Coniochaetone B is rather more interesting. The spectrum is much more complicated, even though it has only one more C–H (the grey one) than coniochaetone A. The reason is that addition of that H atom creates a stereogenic centre and makes the top and bottom faces of the molecule different. Each H in both CH$_2$ groups becomes differentiated from its partner.
The green Hs are coupled to each other ($J = 18$ Hz) and to each of the black Hs with a different coupling constant. One of the green hydrogens also shows a long-range ($J = 1.4$ Hz) W-coupling to the red H. The black Hs are too complex to analyse, even at 600 MHz, but the different couplings to the red Hs are shown by the signal at 5.43 ppm.

**The size of the geminal coupling constant**

The 18 Hz geminal coupling constant between the green protons of coniochaetone B is large, but not unusually so for a geminal coupling. A more typical figure in a six-membered ring might be closer to 14 Hz, and we will see shortly why the value in coniochaetone B is bigger than this. The example below provides an opportunity to examine coupling constants in another example where NMR was essential for determining the structure. The compound is pederin, a toxic amide of the blister beetle *Paederus fuscipes*. After some incorrect early suggestions, the actual structure of the compound was eventually deduced as shown.

We are not going to discuss the full structure elucidation, but will concentrate on the stereochemistry of the right-hand ring. The five (green) protons on the ring gave the signals listed in the margin.

Three of the protons have shifts $\delta_H 3–4$, and are obviously on carbons attached to oxygen atoms. The other two, $\delta_H$ about 2, must be the diastereotopic pair at C5. The coupling of 12 Hz, which appears in both signals, must be the geminal coupling and the other couplings are found in the signals at $\delta_H 3.75$ and 3.85. The signal at $\delta_H 3.75$ has no other couplings and must be from C4 so that leaves $\delta_H 3.85$ for the hydrogen atom at C6, which is also coupled to the hydrogen in

$^a$Exchanges with D$_2$O.
the side chain. The 10 Hz coupling must be axial–axial—the others are all much smaller, meaning there is just the one axial–axial coupling. The left-hand side chain must therefore occupy an axial position as shown in the margin. This is perhaps a bit surprising—it’s large and branched—but the molecule has no choice but to place one of the two side chains axial.

One of the most important compounds from the last 25 years is Taxol, the anti-cancer compound isolated from the bark of the Pacific yew tree. Taxol’s structure has four rings—with eight, six (twice), and four members—and is too complex to analyse in detail, but the NMR spectrum of the closely related compound in the margin gives us the opportunity to illustrate how much geminal couplings in rings may vary and to analyse some of the factors which control this variation. The coupling between the black Hs is 20 Hz while that between the green Hs is just 6 Hz. 20 Hz is a very large coupling constant, even for geminal coupling, and the reason it is so big is the adjacent π bond. If a CH2 group is next to an alkene, aromatic ring, C=O group, CN group, or any other π-bonded functional group, it will have a larger geminal coupling constant. This effect also explains the large 18 Hz coupling in coniochaetone B (p. 819).

But why is the green coupling so small? The reason is the four-membered ring. You saw on p. 814 that vicinal couplings are small in small rings; the same is true of geminal couplings. Another factor comes into play here as well—the adjacent oxygen atom. Electronegative atoms always tend to reduce coupling constants.

The size of 2J and 3J coupling constants

We have now covered all of the important influences on the size of coupling constants. They are:

- dihedral angle: 3J greatest at 180° and 0°; about 0 Hz at 90°
- ring size, which leads to ‘spreading out’ of bonds and lower 2J and lower 3J in small rings
- electronegative atoms, which decrease 2J and 3J coupling constants between protons
- π systems, which increase 2J coupling constants between protons.

Diastereotopic groups

You have now seen several examples where two protons attached to the same carbon are not the same, and it is time to examine more closely the appearance of these CH2 groups in NMR spectra. To do this, we shall have to discuss some aspects of symmetry that build on what you learned in Chapter 14. You will see that there are three possibilities for the symmetry associated with a CH2 group, and these three possibilities have an effect both on the chemistry of the molecule and on what its NMR spectrum will look like.

First, an example in which the two hydrogens are indeed the same. Although the molecule is of course achiral, we may draw one hydrogen coming towards us and one going away, but the two Hs are the same. This is easy to demonstrate. If we colour one H black and one green, and then rotate the molecule through 180°, the black H appears in the place of the green H and vice versa. The rotated molecule hasn’t changed because the other two substituents (OMe here) are also the same.

If we had given out uncoloured models of this molecule with this book, and asked each reader to paint one H green and one H black, we would have no way at all of giving instructions about which to paint what colour. But it wouldn’t matter because, even without these instructions, every reader would produce an identical model, whichever way they painted their Hs.

The correct description for this pair of hydrogen atoms is homotopic. They are the same (homo) topologically and cannot be distinguished by chemical reagents, enzymes, NMR machines, or human beings.

Homotopic groups

Homotopic groups cannot be distinguished by any means whatsoever: they are chemically entirely identical.

What happens when the other two substituents are different? At first sight the situation does not seem to have changed. Surely the two hydrogens are still the same as one another?
In fact, they aren't—not quite. If we had given out uncoloured models of this molecule and just said 'paint one H green and one H black', we would not have got just one type of model. However, this time we could give instructions about which H we wanted which colour. To get the first of these two, we just need to say 'Take the MeO group in your left hand and the Ph group in your right, kink the carbon chain upwards. The hydrogen coming towards you is to be painted black.' All the models produced by readers would then be identical—as long as the readers knew their left from their right. This is a very important point: the green and black hydrogens in this molecule (unlike the first one) can be described only in phrases incorporating the words 'left' or 'right', and are distinguishable only by a system that knows its left from its right.

Human beings are such a system: so are enzymes and the asymmetric reagents you will meet in Chapter 41. But NMR machines are not. NMR machines cannot distinguish right and left—the NMR spectra of two enantiomers are identical, for example. There is no question of enantiomers in the molecule in question—it has a plane of symmetry and is achiral. Nonetheless, the relationship between these two hydrogens is rather like the relationship between enantiomers (the two possible ways of colouring the Hs are enantiomers—mirror images) and so they are called enantiotopic. Enantiotopic protons appear identical in the NMR spectrum.

**Enantiotopic groups**

Enantiotopic groups can be distinguished by systems that can tell right from left, but are still magnetically equivalent and appear identical in the NMR spectrum.

The third situation usually arises when the molecule has a stereogenic centre. As an example we can take the Michael product from the beginning of this section. It is now very easy to distinguish the two hydrogens on each ring carbon atom and, if we want to give instructions on how to paint a model of this molecule, we can just say 'Make all the Hs on the same side of the ring as OMe green, and the ones on the opposite side to OMe black.' We do not need to use the words 'right' or 'left' in the instructions, and it is not necessary to know your right from your left to tell the two types of Hs apart. Ordinary chemical reagents and NMR machines can do it. These Hs are different in the way that diastereoisomers are different and they are diastereotopic. We expect them to have different chemical shifts in the proton NMR spectrum. The same is true of the methyl groups: they too are diastereotopic and we expect them to have different shifts.

**Diastereotopic groups**

Diastereotopic groups are chemically different: they can be distinguished even by systems that cannot tell right from left, and they can appear at different chemical shifts in the NMR spectrum.

**How to tell if protons are homotopic, enantiotopic, or diastereotopic**

What we have said so far explains to you why homotopic and enantiotopic groups always appear identical in the NMR spectrum, but diastereotopic protons may not. Now we will give a quick guide to determining what sort of pair you are dealing with in a given molecule.

The key is to draw your molecule twice. In each drawing (or model if you prefer) replace one of the Hs (we'll assume we're looking at protons, but the argument works for other groups too—Me groups, for example) with an imaginary group 'G'. Write down the first structure you get, with stereochemistry shown. Next, write down the structure you get by replacing the other H with the group G. Now the more difficult bit: identify the stereochemical relationship between the two molecules you have drawn.

* If they are identical molecules, the protons are homotopic.
* If they are enantiomers, the protons are enantiotopic.
* If they are diastereoisomers, the protons are diastereotopic.

This is really just a simpler way of doing what we did with black and green above, but it is easy to do for any molecule. Take the first of our examples, and replace each H in turn by G. These two molecules are identical because just turning one over gives the other: the protons are homotopic.
Now for the next example. The two molecules are not identical: to make one into the other you need to reflect in the plane of the paper, so they are enantiomers, and the Hs are enantiotopic. There is another term we must introduce you to in relation to this molecule, which will become useful in the next chapter, and that is ‘prochiral’. The molecule we started with here was not chiral—it had a plane of symmetry. But by changing just one of the Hs to a different group we have made it chiral. Molecules that are achiral but can become chiral through one simple change are called prochiral.

Now we will choose one of the three pairs of Hs in the cyclohexanone example. The starting molecule is, of course, now chiral, and the two molecules we get when we replace each H by G are now diastereoisomers: one has G and OMe anti, the other syn, and the pairs of hydrogens are diastereotopic. The same is true for the other CH₂ groups. Furthermore, the methyl groups attached to the ring will be diastereotopic too, and we expect them to appear as two 3H singlets.

### Spotting diastereotopic protons in the NMR spectrum

A CH₂ group with diastereotopic Hs isolated from any other Hs will give rise to two signals, one for each H, and they will couple to each other so that the complete signal is a pair of doublets. A typical geminal (2J) coupling constant is 14 Hz—relatively large. Because chemical shift differences (Δδ) between Hs on the same carbon atom tend to be small—usually less than 1 ppm—the signals have Δδ ~ J and are distorted into a ‘roof-topped’ AB system.

Here is an example. The pheromone frontaline is a remarkable compound used by both insects and by elephants to attract a mate. Its structure and ¹H NMR spectrum are shown below.

The red and green hydrogens are diastereotopic, and have no other couplings. They give the pair of doublets at 3.42 and 3.93 ppm., each with J 7 Hz (an AB system) in the ¹H NMR. The coupling constant here is small for 2J—only 7 Hz—but that should not surprise you since we have a five-membered ring and a nearby oxygen atom.

The coupling constant in an AB system is easy to extract—it is the difference in Hz between the two lines highlighted same colour in the spectrum above. But the chemical shifts are not so easily measured. The chemical shift of each proton is at the weighted mean of the two lines—the more distorted the signal, the nearer the chemical shift to that of the larger inner line.

### Diastereotopic protons in acyclic compounds

The same principles apply to open-chain compounds, such as amino acids. All of the amino acids in proteins except glycine are chiral. Glycine has a CH₂ group that gives a singlet in the NMR spectrum as its Hs are enantiotopic. Similarly, the N-benzyl derivative of glycine has a second CH₂ group (NCH₂Ph) that gives another singlet in the NMR spectrum as these Hs too are enantiotopic.
The plane of the paper is a plane of symmetry for both of the CH$_2$ groups of N-benzyl glycine in the way it is drawn here. But for the other amino acids, which are all chiral, the symmetry is different. The $^1$H NMR spectrum of N-benzyl alanine is shown below. There is now no plane of symmetry, so the Hs of the NCH$_2$Ph group are diastereotopic. The CH$_2$ group appears as an AB pattern.

In the way in which the molecule is drawn, the green H is on the same side as the Me group and the brown H on the other. It does not matter that there is free rotation in this molecule—the two diastereotopic protons are never in the same environment so even after averaging over all the conformations available to the molecule they always appear at different chemical shift. If a molecule is chiral, all CH$_2$ groups in that molecule—however flexible it may be and however far they are from any chiral centre—are diastereotopic, and can potentially appear in the spectrum as an AB system.

It is more common to find diastereotopic CH$_2$ groups with neighbours, and an example arises when aspartic acid is dissolved in D$_2$O with NaOD present. The NH$_2$ protons are exchanged for deuterium atoms and do not show up in the spectrum—the molecule exists as its dianion.
**To summarize...**

We have covered a lot of ground in this chapter, and have used the huge topic of saturated heterocycles to explain a lot, not just about the reactivity and conformation of rings. Many of these explanations involved consideration of the alignment of orbitals—we called these stereoelectronic effects. The same analysis allowed us to make sense of the NMR spectra, and in particular the coupling constants, of cyclic molecules, both heterocyclic and carbocyclic. And by thinking about symmetry in these cyclic molecules we were also able to deduce the origins of symmetry-related features (such as diastereotopic protons) in the NMR spectra of acyclic compounds.

The next chapter is the fourth consecutive chapter to take rings as a theme. It will introduce you to practical ways of controlling stereochemistry in cyclic systems—the first step towards making molecules with a particular stereochemistry, which will continue in Chapter 33 and culminate in Chapter 41 on asymmetric synthesis.

**Further reading**

Another reminder: you will find it an advantage to have one of the short books on spectroscopic analysis to hand as they give explanations, comprehensive tables of data, and problems. We recommend D. H. Williams and Ian Fleming, *Spectroscopic Methods in Organic Chemistry*, McGraw-Hill, London, 6th edn, 2007.

**Check your understanding**

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)

\section*{Introduction}

In the last chapter we looked at how the NMR spectra of cyclic molecules tell us a lot about their shape—both their conformation and their configuration. We are now going to go beyond simply studying stereochemistry and start to explain how to control stereochemistry. We have already, in Chapter 27, spent some time looking at controlling one aspect of stereochemistry—double bond geometry. But stereochemistry is about much more than this, and in this chapter and the next we will explain how to make single diastereoisomers and single enantiomers.

We start with stereochemistry in rings. Not only is stereochemistry easier to understand in cyclic compounds, it is also \textit{better behaved} in cyclic compounds. Suppose you were to reduce this ketone to one of the corresponding alcohols.

To achieve a stereoselective reaction at the new stereogenic centre (shown in black) the green stereogenic centre would somehow have to influence the direction of attack of the nucleophile on the $C=O$ group. Separated from it by three bonds, in a molecule with a high degree of flexibility, makes this a very tall order. A more or less 50:50 mixture of the two diastereoisomers would be expected.
However, if we join up the molecule into a ring, as shown in the margin, things are suddenly quite different. (This is not, of course, a chemical reaction—just a thought process!) The cyclic ketone has a fixed conformation controlled by the determination of the tert-butyl group to be equatorial. The two faces of the carbonyl group are therefore clearly quite different, and in fact by careful choice of reducing agent it is possible to attack either at will, giving almost exclusively either the axial or the equatorial alcohol. As we will explain shortly (p. 828) large reagents prefer to approach equatorially while small reagents prefer to approach axially, putting the new OH group into an equatorial position. These are stereoselective reactions and, because the two different outcomes are diastereoisomers, we can call them diastereoselective.

The key to the difference between these two compounds is in their conformations. The six-membered ring of the cyclic ketone has one conformation and the two approaches to the faces of the ketone are very different. In the open-chain compound rotation about all the C–C bonds is possible and very many conformations will be populated. In any one conformation, attack on one face of the ketone or the other may happen to be preferred, but summed over all of them the average selectivity will be close to 1:1. There is all the difference in the world between cyclic and open-chain compounds when it comes to stereoselective reactions.

In this chapter we shall look at reactions happening to cyclic compounds, reactions with cyclic intermediates, and reactions with cyclic transition states. We shall investigate what happens to stereochemistry when two (or even more) rings are joined together at a bond or at an atom. You have already looked in detail at reactions which close rings (Chapter 31, p. 805), and many of the reactions in this chapter you will have met earlier in the book. Our task is to reveal new features and subtleties, and to show you how to use these reactions to control stereochemistry.

**Stereochemical control in six-membered rings**

As you saw in Chapter 16, cyclohexanes benefit from very well defined conformational preferences. Substituents are orientated either axially or equatorially, and usually prefer the equatorial orientation, especially when they are large. The strong preference for substituents to adopt the equatorial position means that when diastereoisomeric cyclohexanes equilibrate by processes such as enolization they may give high selectivity for the all-equatorial compound. For example, this fine perfumery material is made worthless by enolization.

The reason the equilibrium favours the worthless trans isomer (it forms 92% of the equilibrium mixture) is that the two substituents are both in the more stable equatorial positions.
Six-membered rings containing one sp²-hybridized carbon atom: cyclohexanone

If we're interested in the reactions of six-membered rings, then we are going to have to consider what happens to their conformation when they contain reactive functional groups such as carbonyl groups and alkenes—in other words, the effect of introducing sp² C atoms into the ring. For just one sp² carbon atom the simple answer is that nothing changes—the conformation is not significantly altered by the presence of just one sp² centre in a ring. The conformations of methylenecyclohexene and cyclohexanone are shown below.

Six-membered rings with more than one sp² C atom do lose their chair conformation—they become flattened to some degree when there are one or more double bonds included in the ring and we shall come on to those in the next section.

**Axial or equatorial attack is possible on a cyclohexanone**

So, what happens when a cyclohexanone is attacked by a nucleophile? For cyclohexanone itself, the reaction below gives a product which can adopt either of the two conformations shown, with Nu axial or equatorial, depending on the relative size of Nu and OH. This reaction does not tell us much about the attack on the C=O group itself—we can't tell, for example, whether Nu attacked the axial or the equatorial face of the C=O group.

Now think of a nucleophile attacking 4-t-butylcyclohexanone. Since the t-butyl group locks the ring (t-Bu can never be axial), whether Nu is axial or equatorial will depend only on which face of the C=O group it attacks. Attack on the same face as the t-butyl group leaves the nucleophile axial and the hydroxyl group equatorial; attack on the opposite face leaves the nucleophile equatorial and the hydroxyl group axial. The nucleophile is said to attack either in an axial or equatorial manner, depending on where it ends up. It's easier to see this in a diagram.

Now for an observation—we'll try and explain it shortly. In general, large nucleophiles attack equatorially and small nucleophiles attack axially. For example, reduction of 4-t-butylcyclohexanone with lithium aluminium hydride in Et₂O gives 90% of the *trans* alcohol; 90%
of the hydride has added axially. AlH$_4^-$ is quite small as nucleophiles go: to make more of the cis alcohol we need a larger nucleophile—lithium tri-sec-butylborohydride, for example, sold under the name of L-selectride®. This is so large that it attacks only equatorially, yielding typically 95% of the cis alcohol.

Carbon-centred nucleophiles follow the same trend—the table shows that, as size increases from the slender ethynyl anion through primary and secondary organometallics to t-BuMgBr, the axial selectivity drops off correspondingly. PhLi behaves as though it were quite small because it is flat.

Now the difficult part—why? This is a question to which the answer really is not known for certain. It’s certainly true that the direction of approach for axial attack is more hindered than for equatorial attack, and this is certainly the reason large nucleophiles prefer to attack equatorially.

But if this is the case, why do small ones actually prefer to attack axially? There must be another factor that favours axial attack for those nucleophiles small enough to avoid the bad interactions with the other axial hydrogens. At the transition state, the forming –O$^-$ oxygen substituent is moving in either an axial or an equatorial direction. Just as the axial substituent is less favourable than an equatorial one, so is the transition state leading there, and the route leading to the equatorial hydroxyl group is favoured.

When chemists made the drug alphaprodine using the reaction shown below, they found that the combination of the equatorial preference of a methyl group adjacent to C=O and an equatorial preference for attack on the C=O group were enough to favour the formation of one diastereoisomer. Here is the reaction, with the starting material and product represented as a conformational diagram.

We can also represent the reaction in configurational terms. This is less good for explaining the stereoselectivity, but you should always be prepared to turn conformational diagrams into standard configurational ones.
In the next reaction, stereoselectivity is not so good. Zeneca (now AstraZeneca) announced the manufacture of a drug by the addition of a lithiated thiophene to another heterocyclic ketone, which initially gave a mixture of diastereoisomers.

Such a mixture is no good for manufacture of a pure drug, but the compound can be equilibrated in dilute acid by repeated $S_N1$ formation of a tertiary cation and recapture by water so that the required product (which is more stable as it has both Me and the thiophene equatorial) dominates by 92:8 and can be purified by crystallization. The unwanted isomer can be recycled in the next batch.

In these reactions the molecule has a free choice whether to place a substituent in an axial or equatorial position and this is the only consideration because the starting materials in the reactions—ketones or carbocations—have six-membered rings that are already in the chair conformation even though they have one trigonal (sp$^2$) atom in the ring.

**Six-membered rings with two or more sp$^2$ carbons: cyclohexenes**

With more than two trigonal carbon atoms in the ring, a cyclohexene can no longer adopt a chair conformation. At least four of the atoms in the ring must now be in a plane, and the best way to represent this is in the diagrams shown below. The four atoms in the plane are nearest you, with the remaining two placed one above and one below that plane.

Cyclohexene itself flips rapidly between these two conformations, with a barrier of about 22 kJ mol$^{-1}$, about half that of cyclohexane. As in cyclohexane, hydrogen atoms on the saturated carbons of the cyclohexene structure adopt two types of positions, but as they are not quite orientated in the same way as in cyclohexane, we call the two orientations ‘pseudoaxial’ and ‘pseudoequatorial’.

**Only axial attack is possible with cyclohexenes**

These conformations of six-membered rings with more than one trigonal carbon are quite plainly not chairs, and are much less stable than chairs. Anything which allows them to become a chair is likely to be highly favoured, and the stereoselectivity of a reaction is likely
to be driven by the need for the transition state and product to have a chair rather than a boat conformation. This can override the preference for substituents to go into equatorial positions. The choice of axial attack controls the stereoselectivity of reactions of cyclohexenes (and, as you will see, their epoxides), six-membered cyclic enolates, and six-membered cyclic enones.

- The number of trigonal carbon atoms in the ring decides which factors control stereoselectivity
  - Six-membered rings with one trigonal (sp²) carbon atom are already chairs and can undergo axial or equatorial attack.
  - Six-membered rings with two or more trigonal carbon atoms are not chairs and undergo axial attack in order to form chairs rather than boats. The final product may end up with axial or equatorial substitution, but this is not a consideration in the reaction itself.

Alkylations of enolates, enamines, and silyl enol ethers of cyclohexanone usually show substantial preference for axial attack. The enamine of 4-t-butylicyclohexanone, which has a fixed conformation because of the t-butyl group, gives 90% axial alkylation and only 10% equatorial alkylation with n-PrI.

To get at the reason for this result we need to look at the conformation of the enamine intermediate. At this point we shall generalize a bit more and write a structure that represents any enol derivative where X may be OH, O⁻, OSiMe₃, NR₂, and so on. The double bond (2 × sp² centres) in the ring means the conformation is a partially flattened chair, as described above. We place the t-butyl group in an equatorial position because, as with cyclohexanes, it is so bulky it cannot go axial. This means that there is only one conformation to consider—the one shown in the margin.

Now, the electrophile must attack the π system of this conformation, and to do so it has to attack from more or less directly above or below because only then can it interact with one of the lobes of the p orbital at the enol position shown in orange. The need to interact with the π system is the reason cyclohexenes and related compounds react in an axial direction. The top of the molecule looks to be more open to attack so we shall try that approach first.

As the electrophile forms a bond to the trigonal carbon atom, that atom must become tetrahedral and it does so by forming a vertical bond upwards. The result is shown in the diagram—the ring turns into a twist-boat conformation. Now, of course, after the reaction is over, the ring can flip into a chair conformation and the new substituent will then be equatorial, but that information is not present in the transition state for the reaction. We could say that, at the time of reaction, the molecule doesn’t ‘know’ it can later be better off and get the substituent equatorial: all it sees is the formation of an unstable twist boat with a high-energy transition state leading to it.

Attack from the apparently more hindered bottom face makes the trigonal carbon atom turn tetrahedral in the opposite sense by forming a vertical bond to the electrophile downwards. The ring goes directly to a chair form with the electrophile in the axial position.
When the carbonyl group is restored by hydrolysis (if necessary—with an enolate X is already O) the ring need not flip: it’s already a chair with the t-butyl equatorial, and the new substituent is axial on the chair. This is the observed product of the reaction.

It’s important that you understand what is going on here. The reagent has to attack from an axial direction to interact with the p orbital. If it attacks from above, the new substituent is axial on an unstable twist boat. If it attacks from below, the new substituent is axial on a chair—granted, this is not as good as equatorial on a chair, but that’s not an option—it has to be axial on something, and a chair is better than a twist boat. So this is the product that forms.

It’s just hard luck for the substituent that it can’t know that if it did weather it out on the twist boat it could later get equatorial—it plumps for life on the chair and so has to be content with ending up axial.

Here is an example with an unsaturated carbonyl compound as an electrophile: the reaction is a Michael addition. The ketone here is slightly different—it has the t-butyl group in the 3- rather than the 4-position, and the reacting centre becomes quaternary during the Michael reaction. But the result is still axial attack.

This result is more impressive because the large electrophile ends up on the same side of the ring as the t-butyl group, so the stereoselectivity cannot be based on any simple idea of reaction on the less hindered side of the ring. It is genuine axial attack, as the conformational diagram of the product confirms.

Cyclohexenones are even flatter than cyclohexenes, but it is convenient to draw them in a similar conformation. Conjugate addition to the substituted cyclohexenone in the margin gives the trans product.

This is also axial addition to form a chair directly (rather than a twist boat) with the nucleophile approaching from the bottom. We must draw the ring as a flattened chair.

The 5-alkyl cyclohexenone that we have chosen as our example gives the best results. The mechanism suggests that the enolate intermediate is protonated on the top face (axial addition again), although we cannot tell this because the product has no stereogenic centre there. But, if we carry out a tandem reaction with the enolate trapped by a different electrophile, it becomes clear that the product is again that of axial attack.
We shall end this section on conformational control in six-membered rings with the preparation of a useful chiral molecule, 8-phenylmenthol, from the natural product \((R)-(+)\)-pulegone. The first step is a copper-promoted conjugate addition to an exocyclic alkene. A new stereogenic centre is formed by protonation of the enolate intermediate but with virtually no stereoselectivity.

Now thermodynamic control can be brought into play. The position next to the ketone can be epimerized via the enolate to give the more stable isomer with both substituents equatorial. This improves the ratio of diastereoisomers from 55:45 to 87:13.

Now the ketone can be reduced with a small reagent (see p. 826)—Na in \(i\)-PrOH works well—to put the hydroxyl group equatorial. This means that all the product has OH \(\text{trans}\) to the large group next to the ketone, although it is still an 87:13 mixture of diastereoisomers with respect to the relative configuration at the centre bearing Me.

These alcohols can be separated (they are, of course, diastereoisomers and not enantiomers) and the major, all-equatorial, one is the useful one. This is an impressive example of conformational control by thermodynamic and by kinetic means originating only from a distant methyl group in a six-membered ring.

Reactions on small rings

The conformational principles which apply to rings other than six-membered ones are rather more sketchy because only six-membered rings adopt well-defined chair (or, for cyclohexenes, half-chair) conformations. But we can still give you some general guidelines and principles, and illustrate them with some important examples. We will look in detail at four- and five-membered rings.
**Four-membered rings can be flat**

Saturated four-membered rings have a slightly bent conformation but four-membered lactones are flat. The enolates of these lactones can be made in the usual way with LDA at $-78 \, ^\circ C$ and are stable at that temperature, and they react with electrophiles just as you saw in Chapter 25. If the $\beta$-lactone has a substituent already then there may be a choice as to which face of the enolate is attacked by an electrophile. In the example below, simple alkylation with a variety of alkyl halides gives essentially only one diastereoisomer of the product.

![Diastereoselectivity reactions of racemic compounds](image)

The enolate, as we have seen, is planar, and the phenyl group is in the plane (which is why it doesn’t matter which of the two possible diastereoisomers of the starting material is used). The isopropyl group is the only thing out of the plane. The electrophile simply adds to the face of the enolate not blocked by the isopropyl group. This is a very simple case of a diastereoselective reaction.

**Lactone enolates**

This lithium enolate works well even though it might be expected to be unstable because of a simple elimination reaction. In general, it is not possible to make open-chain lithium enolates with $\beta$ oxygen substituents like this because they do undergo elimination.

![Lactone enolates](image)

But, in the four-membered ring, the $p$ orbitals of the enolate and the C–O single bond are orthogonal (see diagram below) so that no interaction between them, and no elimination, can occur. In the terminology of Baldwin’s rules (Chapter 31, p. 810) it would be a disfavoured 4-endo-trig reaction.

![Diastereoselective reactions of racemic compounds](image)

Reduction of substituted four-membered ring ketones is usually reasonably stereoselective. If the substituent is in the 3-position and small reagents like NaBH$_4$ are used, the cis isomer is favoured. Like saturated four-membered rings, cyclobutanones are slightly puckered to reduce eclipsing interactions between hydrogen atoms on adjacent carbon atoms, but attack of the reducing agent still occurs from the direction away from the other substituent to give the cis product.
Five-membered ketones are flexible

A saturated five-membered ring has a conformation often called an ‘envelope’. It looks a bit like an opened envelope with one atom at the point of the flap. The arrangement closely matches what you get if you cut one atom out of a cyclohexane ring. At any one moment, one of the carbon atoms is at the point of the envelope but rapid ring flipping equilibrates all these conformers so that all five atoms are, on average, the same.

Substituted cyclopentanes can have substituents in pseudoaxial or pseudoequatorial positions (in other words, they are somewhat like the axial and equatorial positions in a cyclohexane), but rapid equilibration means that overall we have a very flexible and labile system. As a result, reduction of 2-substituted cyclopentanones may not be very stereoselective. What selectivity there is (about 3:1) in the reduction of 2-methylpentanone with LiAlH₄ favours pseudoaxial attack in the conformation drawn, as is reasonable for a small nucleophile.

The use of a much more bulky reducing agent such as LiBH(s-Bu)₃ dramatically reverses and increases the stereoselectivity. Essentially only the cis compound is formed.

Regard five-membered rings with two or more sp³ carbons as flat

When there are two or three trigonal carbons in the ring, the ring is flatter and reactions such as enolate alkylation and conjugate addition give excellent stereoselectivity even with a simple cyclopentane ring. Unsaturated five-membered lactones (known as ‘butenolides’) give a very clear illustration of stereochemically controlled conjugate addition. There is only one possible stereogenic centre and the ring is almost planar so we expect nucleophilic attack to occur from the less hindered face. Cuprates are good nucleophiles for this reaction and here Me₂CuLi adds to the unsaturated lactone.

With a single enantiomer of the starting material below, the product is the single enantiomer of an insect pheromone.

It is not even necessary to have a stereogenic centre in an unsaturated ring if we want to create stereochemistry. A tandem conjugate addition and alkylation creates two new stereogenic centres in one operation. The conjugate addition of a lithium cuprate makes a lithium enolate, which will react in turn with an alkyl halide. The product is usually trans.
The key step is the alkylation of the enolate intermediate. Enolates in five-membered rings are almost flat and the incoming orange allyl bromide prefers the less hindered face away from the recently added green vinyl group.

Our main example of enolate reactions in five-membered rings is one of some general importance. It illustrates how stereochemical information can be transmitted across a ring even though the original source of that information may be lost during the reaction. That may sound mysterious, but all will become clear. The first reaction is to make a five-membered cyclic acetal from an optically active hydroxy-acid. Our example shows (S)-(+) -mandelic acid reacting with t-BuCHO.

\[
\text{(S)-(+) -mandelic acid} + \text{H}^+ \text{cat.} \rightarrow \text{24:1 cis:trans} \rightarrow \text{both substituents pseudoequatorial}
\]

Acetal formation involves nucleophilic attack of the OH group on the aldehyde so there is no change at the stereogenic centre. The stereochemistry of the new (acetal) centre may surprise you—why should the cis isomer be so favoured? This is a conformational effect as both substituents can occupy pseudoequatorial positions.

Now, if we make the lithium enolate with LDA, the original stereogenic centre is destroyed as that carbon becomes trigonal and planar. The only stereogenic centre left is the newly introduced one at the acetal position.

The ring is now essentially flat, owing to the C=C bond within it, and reaction of the enolate with an electrophile is again a simple matter of addition to the face of the enolate opposite to the t-butyl group.

If the acetal is now hydrolysed, the new stereogenic centre is revealed as an alkylated version of the starting material. It may appear that the alkylation has happened stereospecifically with retention, but what has really happened is that the new stereogenic centre in the acetal intermediate has relayed the stereochemical information through the reaction.

Five-membered rings also allow us to explore electrophilic attack on alkenes. A simple 4-substituted cyclopentene has two different faces—one on the same side as the substituent and one on the opposite side. Epoxidation with a peroxy-acid occurs preferentially on the less hindered face.

The conjugate addition forms a lithium enolate regiospecifically, and that was why you met this sequence in Chapter 25. We showed you a dramatic use of the stereoselectivity there as well, in a synthesis of a prostaglandin (p. 604).

Check that you can write the mechanisms for acetal formation (Chapter 11). Acetal formation is under thermodynamic control so the product produced is the more stable.

Note that this reaction is diastereoselective—but neither starting material nor products are chiral. Diastereoselectivity need have nothing to do with chirality!
In the transition state (marked ‡) the peroxyacid prefers to be well away from R, even if R is only a methyl group (the selectivity is 76:24 with R=Me).

The opposite stereoselectivity can be achieved by bromination in water. The bromonium ion intermediate is formed stereoselectively on the less hindered side and the water is forced to attack stereospecifically in an SN2 reaction from the more hindered side.

Treatment of the product with base (NaOH) gives an epoxide by another SN2 reaction in which oxygen displaces bromide. This is again stereospecific and gives the epoxide on the same side as the R group.

Two substituents on the same side of a five-membered ring combine to dictate approach from the other side by any reagent, and the two epoxides can be formed each with essentially 100% selectivity.

**Regiochemical control in cyclohexene epoxides**

The two reactions above illustrate two important ways of making an epoxide. We are now going to look in a little more detail at what happens when epoxides are opened—a reaction that is essentially the reverse of the epoxide-closing reaction you have just seen. Here are both reactions with the epoxide fused to a cyclohexane ring:

Epoxides can be formed from compounds containing an adjacent hydroxyl group and a leaving group by treatment with base. The epoxide formation is an intramolecular SN2 reaction, and as with any SN2 substitution, inter- or intramolecular, the incoming nucleophile must still attack into the $\sigma^*$ orbital of the leaving group. And the only way that can happen, as you can see from the diagrams below, is (a) if the hydroxyl group and leaving group are trans to one another and (b) if the hydroxyl group and leaving group are both orientated axially. For the trans diastereoisomer, the groups can of course adopt either a diequatorial or a diaxial arrange-
ment (the diequatorial arrangement is favoured, as you saw in Chapter 16) but only the diaxial can react. The cis diastereoisomer cannot form an epoxide.

\[
\begin{align*}
\text{trans-2-bromocyclohexanol} & \quad \text{cis-2-bromocyclohexanol} \\
\text{both groups equatorial} & \quad \text{with two groups axial, oxygen can attack the C–Br} \sigma^* \text{orbital} \\
\text{epoxide can’t form because oxygen can’t reach} \sigma^* \text{orbital} & \quad \text{Br axial, O– equatorial} \\
\end{align*}
\]

How should we draw this epoxide fused to a six-membered ring? It is impossible for the CO bonds of the product epoxide ring to adopt perfectly axial and equatorial positions. If you make a model of cyclohexene oxide (as we can call this epoxide) you will see that the ring is a slightly deformed chair—in fact it is like the half-chair conformation of cyclohexene, in which four of the carbon atoms are in the same plane (you met this on p. 829).

The usual way of drawing cyclohexene oxide is shown below: the distortion due to the three-membered ring changes the orientation of the axial and equatorial hydrogens next to the ring—they are pseudoaxial and pseudoequatorial. The hydrogens on the back of the ring (this part of the ring remains about the same as in the chair conformation) can be still considered as ‘normal’ axial and equatorial hydrogens.

You saw above that the epoxide-forming reaction is essentially the reverse of the epoxide-opening reaction. If we took a snapshot of the transition state for either reaction, we would not be able to tell whether it was the RO\(^-\) that was attacking the C–X \(\sigma^*\) orbital to form the epoxide with X\(^-\) as a leaving group, or a nucleophile X\(^-\) attacking the C–O \(\sigma^*\) orbital of the epoxide to form a ring-opened alcohol. In other words, the transition state is the same for both reactions.
Since ring closure is possible only when the starting material is diaxially substituted, this has to mean that ring opening is similarly possible only if the product is diaxial. This is a general principle: ring opening of cyclohexene oxides always leads directly to diaxial products. The diaxially substituted product may then subsequently flip to the diequatorial one, but it is always the one that is initially formed.

How do we know this to be true? If the ring bears a bulky substituent, ring flipping is impossible and the diaxial product has to stay diaxial. An example is nucleophilic attack of halide on the two epoxides shown below. The fact that the ring is a piperidine, rather than a cyclohexane, does not matter. The equatorial phenyl group fixes the conformation, and the regiochemistry of the epoxide opening with azide depends only on the relative stereochemistry of the starting material.

Points to note:
- The nucleophile must attack from the opposite side of the epoxide, allowing it to put electrons into the C–O $\sigma^*$ orbital. This means that the nucleophile and hydroxyl group always end up trans in the product.
- The phenyl group locks the conformation of the epoxide. It stays equatorial, so we only have one epoxide conformation to consider in each case.
- In each case the epoxide opens only at the end that gives the diaxially substituted chair. Ring opening at the other end would still give a diaxially substituted product, but it is a diaxially substituted high-energy twist-boat conformation. The twist boat can, in fact, flip to give an all-equatorial product, but in a kinetically controlled
process such as this, it is the barrier to reaction that matters, not the stability of the final product.

Some general observations on stereo- and regioselectivity in six-membered rings:

- Six-membered rings which are not already a chair (such as cyclohexenes and cyclohexene oxides) react in such a way that they immediately become a chair.
- They do so by reacting from an axial direction: this may also dictate the regioselectivity of the reaction.
- Six-membered rings which are chairs already (such as cyclohexanones) remain a chair, and react from either the axial or equatorial direction according to the size of the attacking reagent.

Stereoselectivity in bicyclic compounds

We have just looked at the way the reactivity of an epoxide gains additional subtleties when it is fused into a bicyclic structure with a six-membered ring. We’re now going to look more generally at bicyclic compounds and their reactivity, and consider some features of their stereoselective reactions.

Bridged bicyclic rings

There are broadly three kinds of bicyclic compounds. If we imagine adding a second five-membered ring to one already there, we could do this in a bridged, fused, or spiro fashion, as you see in the margin. Bridged bicyclic compounds are just what the name implies—a bridge of atom(s) is thrown across from one side of the ring to the other. Fused bicyclic compounds have one bond common to both rings, while spiro compounds have one atom common to both rings.

You will notice that these three types of bicyclic compounds with five-membered rings have different numbers of atoms added to a ‘parent’ five-membered ring. The bridged compound has two extra atoms, the fused compound three, and the spiro compound four. These are marked in green with the original five-membered ring in red. We shall consider stereoselectivity in each of these types of bicyclic ring systems, starting with bridged structures.

The bridged ring shown in the margin is known as norbornane: it’s a simple but very important skeleton on which many other structures are based, and it’s worth spending a moment learning how to draw it convincingly. The instructions in the box overleaf tell you how! Another way of looking at norbornane is as a six-membered ring held in a boat conformation by a one-carbon bridge. The bridge has to be axial at both bridgehead positions (or it wouldn’t be able to form a ring) so the cyclohexane has no choice but to be a boat.

Naming bicyclic compounds

As usual we shall not spend too long on nomenclature, but you may hear norbornane structures referred to as ‘bicyclo[2.2.1]heptanes’. The ‘bicyclo’ and ‘heptane’ parts are self explanatory. The numbers (always separated by dots) refer to the lengths of the bridges linking the two bridgehead carbons. The other two compounds in the margin above are thus bicyclo[3.3.0]octane and spiro[4.4]nonane.
How to draw norbornane structures

The easiest way to draw a convincing norbornane is to start with the bridge: draw a sort of skewed upwards chevron as shown in 1. Then join the ends of the chevron with three bonds, as in 2, making sure to break one of them as it passes behind the chevron, to give an impression of the three-dimensional shape of the molecule. Finally, link the second ring round to the right, 3.

A selection of important bridged bicyclic compounds is shown in the margin. Bridged structures (sometimes called cage structures) are generally very rigid, spending most of their time in a single, well-defined conformation, and this rigidity is reflected in the stereochemistry of their reactions. For example, attack on norbornanone occurs predominantly from the side of the one-atom bridge (the green arrow) rather than the two-atom bridge (the orange arrow).

This selectivity is completely reversed in camphor because the one-atom bridge then carries two methyl groups. One of these must project over the line of approach of the hydride reducing agent.

The two methyl groups on the bridge of the camphor molecule are key features in stereoselective reactions—take them away and the result often changes dramatically. This bicyclic system, with and without methyl groups, has been so widely used to establish stereochemical principles that the two faces of, say, the ketone group in camphor, or the C=C double bond in norbornene (the alkene derivative of norbornane) have been given the names endo and exo. These refer to inside (endo) and outside (exo) the boat-shaped six-membered ring shown in black. In general, reactions of norbornane-type structures occur from the less hindered exo face, but the methyl groups of camphor reverse this selectivity to favour endo attack:

In a similar style, epoxidation of the two alkenes is totally stereoselective, occurring exo in norbornene and endo when methyl groups are present on the bridge. These stereoselectivities would be remarkable in a simple monocyclic compound, but in a rigid bridged bicyclic structure they are almost to be expected.
Reactions that break open bridged molecules can preserve stereochemistry

Some powerful oxidizing agents are able to cleave C–C bonds. Oxidation of camphor with concentrated nitric acid cleaves a C–C bond adjacent to the C=O group and produces a diacid known as camphoric acid. The usual reagent is nitric acid (HNO₃) and oxidation goes via camphor’s enol.

Because the bridge holds the molecule in a fixed conformation, the cleaved diacid has to have a specific stereochemistry. There is no change at the stereogenic centres, so the reaction must give retention of configuration. We can confidently write the structure of camphoric acid with cis-CO₂H groups, but any doubt is dispelled by the ability of camphoric acid to form a bridged bicyclic anhydride.

Fused bicyclic compounds

trans-Fused rings

The ring junction of a fused 6,5-membered ring system can have cis or trans stereochemistry, and so can any pair of larger rings. For smaller rings, trans 5,5- and 6,4-ring junctions can be made, with difficulty, but with smaller rings trans ring junctions are essentially impossible.

The trans-fused 6,6 systems—trans-decalins—have been very widely studied because they form an important part of the structure of steroids. Their conformation was discussed in Chapter 16: they prefer a trans ring junction as trans-decalins have all-chair structures with every bond staggered from every other bond. We can show this by giving a 6,6 system the choice: reducing this enone with lithium metal gives a lithium enolate (Chapter 25). Protonation of this anion with the solvent (liquid ammonia) gives a trans ring junction.
The lithium enolate remains and can be alkylated with an alkyl halide in the usual way. When there are hydrogen atoms at both ring junction positions, axial alkylation occurs just as you should now expect, and a new ketone with three stereogenic centres is formed with >95% stereoselectivity.

However, if there is anything else—even a methyl group—at the ring junction, so that axial approach would give a bad 1,3-diaxial interaction in the transition state, the usual stereoselectivity is overridden and the reaction switches to alkylation on the other face:

**cis-Fused rings**

Almost any cis-fused junction from 3,3 upwards can be made. Even bicyclo[1.1.0]butane exists, although it is not very stable. cis-Fused 4,5, 4,6, and 5,5 systems are common and are much more stable than their trans isomers.

Any method of making such bicyclic compounds will therefore automatically form this stereochemistry. Consider this hydrogenation:

You can think of cis-fused rings as looking like a butterfly or an open book. The key to stereoselectivity in their reactions is that everything happens on the outside (on the cover of the book—the exo face). Nucleophiles add to carbonyl groups from the outside, enolates react with alkyl halides or Michael acceptors on the outside, and alkenes react with peroxyacids on the
outside. Notice that this means the same side as the substituents at the ring junction. The rings are folded away from these ring-junction substituents, which are also on the outside.

A real example comes in the acylation (Chapter 26) of the enolate from the keto-acetal below. The molecule is folded downwards and the enolate is essentially planar, so the outside face is the top face as drawn. Addition presumably occurs entirely from the outside, although the final stereochemistry of the product is controlled thermodynamically because of reversible enolization of the product, allowing the black ester group to adopt the less hindered outside position.

Reduction of the ketone product also occurs exclusively from the outside and this has the surprising effect of pushing the new OH group into the inside position. Attack from the inside is very hindered in this molecule because one of the acetal oxygen atoms is right on the flight path.

The important metabolite biotin has a cis bicyclic structure in which an alkyl chain lies on the more hindered face of the molecule, and any successful synthesis has to address this particular problem. You saw in Chapter 27 that sulfur stabilizes an adjacent anion, but the direct alkylation of the sulfide below is no good because the new alkyl group will go exo. Instead, the sulfide was oxidized to a sulfoxide from the exo face, giving an 8:1 ratio of exo:endo sulfoxides. Alkylation of the cyclic sulfoxide results in trans stereochemistry between the new alkyl group and the sulfoxide oxygen atom, forcing formation of the desired (endo) product. The synthesis is diastereoselective—but not enantioselective since there is no way of distinguishing the left and right sides of the symmetrical sulfoxide.

A simple example of epoxidation occurs with a cyclobutene fused to a five-membered ring. This is a very rigid system and attack occurs exclusively from the outside to give a single epoxide in good yield.
Epoxidation is stereospecific and cis—both new C–O bonds have to be on the same face of the old alkene. But Chapter 19 introduced you to several electrophilic additions to alkenes that were stereospecific and trans, many of them proceeding through a bromonium ion. If stereospecific trans addition occurs on a cis-fused bicyclic alkene, the electrophile will first add to the outside of the molecule, meaning the nucleophile will then be forced to add from the inside. A telling example occurs when the 5,4 fused unsaturated ketone below is treated with N-bromoacetamide in water.

The bromonium ion is formed on the outside of the rigid structure and the water is then forced to add from the inside to get trans addition. As well as exhibiting stereospecificity (trans addition) and stereoselectivity (bromonium forms on outside), this reaction also exhibits regioselectivity in the attack of water on the bromonium ion. Water must come from inside, and it attacks the less hindered end of the bromonium ion.

After protection of the OH group, treatment with base closes a three-membered ring to give a remarkably strained molecule. The ketone forms an enolate and the enolate attacks the alkyl bromide intramolecularly to close the third ring. This enolate is in just the right position to attack the C–Br bond from the back, precisely because of the folding of the molecule.

Inside/outside selectivity may allow the distinction between two otherwise similar functional groups. The cis-fused bicyclic diester below may look at first rather symmetrical but ester hydrolysis leaves one of the two esters alone while the other is converted to an acid.

Only the outside ester—on the same side as the ring junction hydrogens—is hydrolysed. In the mechanism for ester hydrolysis, the rate-determining step is the attack by the hydroxide ion so the functional group increases in size in the rate-determining step. This will be much easier for the ester in the outside than for the one inside the half-open book.

The end result is again that the larger of the two groups is on the inside! There are other ways to do this too. If we alkylate the enolate of a bicyclic lactone, the alkyl group (black) goes on...
the outside as expected. But what will happen if we repeat the alkylation with a different alkyl group? The new enolate will be flat and the stereochemistry at the enolate carbon will be lost. When the new alkyl halide comes in, it will approach from the outside (green) and push the alkyl group already there into the inside.

Should you wish to reverse the positions of the two groups, you simply add them in the reverse order. Whichever group is added first finishes on the inside; the other finishes on the outside.

Reactions of cis-decalins

You saw in Chapter 16 that while trans-decalins are rigid, cis-decalins can flip rapidly between two all-chair conformations. During the flip, all substituents change their conformation. The substituent R is axial on ring B in the first conformation of cis-decalin shown below but equatorial in the second. The ring junction Hs are always axial on one ring and equatorial on the other. The green hydrogen is equatorial on ring A and axial on ring B in the first conformation and vice versa in the second. Of course, they are cis in both. Because R gets equatorial, the second conformation is preferred in this case.

A standard reaction that gives substituted decalins is the Robinson annelation (Chapter 26). A Robinson annelation product available in quantity is the keto-enone known sometimes as the Wieland–Miescher ketone and used widely in steroid synthesis. The non-conjugated keto group can be protected or reduced without touching the more stable conjugated enone.

If either of these products is reduced with hydrogen and a Pd catalyst (the alcohol is first made into a tosylate), the cis-decalin is formed because the enone, although flattened, is already folded to some extent. A conformational drawing of either molecule shows that the top surface is better able to bind to the flat surface of the catalyst.
Each of these products shows interesting stereoselective reactions. The ketal can be converted into an alkene by Grignard addition and E1 elimination, and then epoxidized. Everything happens from the outside as expected, with the result that the methyl group is forced inside at the epoxidation stage.

Treatment of the other product, the keto-tosylate, with base leads to an intramolecular enolate alkylation—a cyclization on the inside of the folded molecule that actually closes a four-membered ring. The reaction is easily seen in conformational terms and the product cannot readily be drawn in conventional diagrams.

A similar reaction happens on the epoxide to produce a beautiful cage structure. This time it is a five-membered ring that is formed, but the principle is the same—the molecule closes across the fold rather easily. The new stereogenic centres can only be formed with this configuration: no other stereoisomer would be a feasible structure.

---

**A summary of stereoselective reactions that occur on cis-fused rings**

1. **Reactions on the outside.**
   - Nucleophilic additions to carbonyl groups in the ring.
   - Reactions of enolates of the same ketones with electrophiles: alkyl halides, aldols, Michael additions.
   - cis-Additions to cyclic alkenes: hydrogenation, hydroboration, epoxidation.

2. **Reactions on the outside and then the inside.**
   - trans-Additions to cyclic alkenes: bromination, epoxidation, and epoxide opening.

3. **Reactions on the inside.**
   - Bond formation across the ring(s).

---

**Spirocyclic compounds**

Spirocyclic rings meet at one single atom. This means that the two rings are orthogonal about the tetrahedral atom that is common to both. Even symmetrical-looking versions are unexpectedly chiral. The compound in the margin, for example, is not superimposable on its mirror image, and its symmetry is similar to that of an allene (see Chapter 14).

These sorts of compounds may look rather difficult to come by, but some simple ones are readily made. Cyclization of this keto-acid with polyphosphoric acid leads to a spirocyclic diketone. The *spiro* compound is formed because the more substituted enol is preferred in acid solution.
It is much more difficult to pass stereochemical information from one ring to the other in spirocyclic compounds because of the orthogonality of the rings. Still, some reactions are surprisingly stereoselective—one such is the reduction of the spirocyclic diketone that we made a moment ago. Treatment with LiAlH₄ gives one diastereoisomer of the spirocyclic diol.

The diol can be resolved and used to make the very simple spiro-diene as a single enantiomer. The diene is chiral even though it has no chiral centre because it does not have a plane of symmetry.

Reactions with cyclic intermediates or cyclic transition states

Rings are so good at controlling stereochemistry (as you have seen) that it’s well worth introducing them where they are not really necessary in the final product, simply in order to enjoy those high levels of stereochemical control. In the rest of this chapter we shall consider the use of temporary rings in stereochemical control: these might be cyclic intermediates in a synthetic pathway, or cyclic reaction intermediates, or even merely cyclic transition states. All aid good stereocontrol. We shall concentrate on examples where the ring reverses the normal stereoselectivity so that some different result is possible.

Tethered functional groups can reach only one side of the molecule

The proverbial donkey starved to death in the field with two heaps of hay because it could not decide which one to go for first. If the donkey had been tethered to a stake near one heap it would have been able to reach that heap alone and it could have feasted happily.

This principle can be applied to molecules. If a nucleophile is joined to the group it is to attack by a short chain of covalent bonds, it may be able to reach only one side. We can illustrate this idea with a reaction you met in Chapter 24: iodolactonization. To remind you, iodolactonization involves treating a non-conjugated unsaturated acid with iodine in aqueous NaHCO₃. The product is an iodolactone.

The cyclization reaction is a typical two-stage electrophilic addition to an alkene (Chapter 19) with attack by the nucleophile at the more substituted end of the intermediate iodonium ion. The ring opening is a stereospecific Sₘ,2 and the stereochemistry of the alkene will be reproduced in the product.

In Chapter 14 we explained that planes of symmetry, not chiral centres, are the things to look for when deciding whether or not a compound is chiral.

Iodolactonization is described on p. 569.
The starting acid contains an E alkene, giving a trans iodonium ion. Inversion occurs in the attack of the carboxylate anion on the iodonium ion and we have shown this by bringing the nucleophile in at 180° to the leaving group, with both bonds in the plane of the paper. A single diastereoisomer of the iodolactone results from a stereospecific reaction.

Things get more interesting again when the starting material is cyclic. The iodolactonization below gives only one diastereoisomer.

The relationship between the two stereogenic centres on the old alkene is not an issue—inversion during opening of the iodonium ion means that the I and the O must lie trans. But during the cyclization the carboxylic acid can attack only the nearer side of what was the double bond—in other words the bridge in black has no choice but to be cis across the red six-membered ring. The reason for this is that, while formation of the iodonium ion is reversible, only the iodonium ion with the I and CO$_2$H groups trans to each other can cyclize. Tethering the nucleophilic CO$_2$H group to the alkene dictates the stereochemistry of the product.

This reaction can be used to solve a general problem in the synthesis of steroids: the construction of a diketone with trans-fused 6,5 rings and a quaternary carbon atom at the ring junction. One solution to this problem uses the lactone just made.

The lactone makes a good temporary tether because it can be hydrolysed or reduced to break the ring at the C–O bond and reveal new stereogenic centres on the old structure. In this sequence the lactone ring controls all the subsequent stereochemistry of the molecule in two ways: it fixes the conformation rigidly in one chair form—hence forcing the iodide to be axial—and it blocks one face of the ring. From the lactone above, an alkene is introduced by E2 reaction on the iodide. This stereospecific reaction requires an anti-periplanar H atom so it has to take the only available neighbouring axial hydrogen atom, shown in green. The brown and orange hydrogens are not anti-periplanar and anyway elimination with the brown one would produce a bridgehead alkene.

The resulting alkene has its top face blocked by the lactone bridge so epoxidation occurs entirely from the bottom face.
Now the epoxide is opened with HBr. Only the trans diaxial opening product is possible, so the bromide ion is forced to attack from the top face.

![Diagram of ring opening with HBr]

Do you see how the functional groups are being pushed round the ring? This process is extended further by a second elimination, after protection, which again seeks out the only neighbouring axial hydrogen.

![Diagram of second elimination]

The protecting silyl group is removed in acid, ready for the next important reaction: a Michael addition requiring the alcohol to be oxidized to a ketone. Allylic (or benzylic) alcohols can be oxidized by manganese dioxide, and with three atoms now trigonal the ring becomes even further flattened. But-3-enyl Grignard reagent is added with Cu(I) catalysis to make sure that conjugate addition occurs. Conjugate addition normally gives the axial product, as we saw earlier, and fortunately this is not the direction blocked by the bridge.

![Diagram of Michael addition]

The bridge has now done its work and is removed by zinc metal reduction. This reaction removes leaving groups on the atoms next to carbonyl groups. In this case it is the axial carboxylate that is driven out by the zinc. The released carboxyl group is esterified.

![Diagram of zinc metal reduction]

The last stages are shown below. The ketone is protected, and the alkene oxidized to a carbonyl group by ozonolysis (Chapter 19). The diester can be cyclized by a Claisen ester condensation (Chapter 26). The stereogenic centres in the ring are not affected by any of these reactions so a trans ring junction must result from this reaction. After ester hydrolysis, HCl decarboxylates the product and removes the protecting group.
It is not easy to set up a trans-fused 5,6 system. In this sequence the molecule is effectively tricked into making the trans ring junction by the work done with the lactone tether.

**Cyclic transition states can reverse normal stereoselectivity**

Formation of a ring in an intermediate is a means of enforcing a certain stereochemistry—the example you have seen made use of a lactone. But even transient formation of a ring in a cyclic transition state can be enough to control stereochemistry highly effectively. You will see further examples in the next chapter, but here we just present one type of reaction with this property: epoxidation.

Of course epoxidation reactions form rings, and you have seen examples of epoxidations with \( m \)-CPBA even in this chapter (p. 848) of alkenes such as cyclohexene. We pointed out in Chapter 19 that epoxidation is stereospecific because both new C–O bonds form to the same face of the alkene.

If we block one face of the ring with a substituent—even quite a small one, such as an acetate group—epoxidation becomes stereoselective for the face *anti* to the substituent already there.

![Diagram of epoxidation](image)

But there is one important exception to this rule, when the substituent is a hydroxyl group. When an allylic alcohol is epoxidized, the peroxy-acid attacks the face of the alkene *syn* to the hydroxyl group, even when that face is more crowded. For cyclohexenol the ratio of *syn* epoxide to *anti* epoxide is 24:1 with \( m \)-CPBA and it rises to 50:1 with CF\(_3\)CO\(_2\)H.

![Diagram of epoxidation with hydroxyl group](image)

The reason is shown in the transition state: the OH group can hydrogen bond, through the H of the alcohol, to the peroxy-acid, stabilizing the transition state when the epoxidation is occurring *syn*. This hydrogen bond means that peroxy-acid epoxidations of alkenes with adjacent hydroxyl groups are much faster than epoxidations of simple alkenes, even when no stereochemistry is involved.

Peroxy-acids work for epoxidizing allylic alcohols *syn* to the OH group, but another reagent is better when the OH group is further from the alkene. 4-Hydroxycyclopentene, for example, can be converted into either diastereomer of the epoxide. If the alcohol is protected with a large group such as TBDM (\( t \)-butyl-dimethylsilyl), it becomes a simple blocking group and the epoxide is formed on the opposite face of the alkene. The selectivity is reasonable (83:17) given that the blocking group is quite distant. But if the OH group is not blocked at all but left free, and the epoxidation reagent is the vanadium complex VO(acac)\(_2\) combined with \( t \)-BuOOH, the *syn* epoxide is formed instead. The vanadyl group chelates reagent and alcohol, and delivers the reactive oxygen atom to the same face of the alkene as shown.
In both epoxidation examples, the stereoselectivity is due to the cyclic nature of the transition state: the fact that there is a hydrogen bond or O–metal bond ‘delivering’ the reagent to one face of the alkene. Effectively we have moved on from the tethered nucleophiles of the last section to (transiently) tethered reagents. This is a very important concept, and we revisit it in the next chapter: cyclic transition states are the key to getting good stereoselectivity in reactions of acyclic compounds.

To summarize...

Diastereoselectivity in rings generally follows a few simple principles:

- Flattened three-, four-, or five-membered rings, especially ones with two or more trigonal carbons in the ring, are generally attacked from the less hindered face.
- Flattened six-membered rings with two or more trigonal carbons in the ring (that is, which are not already a chair—so six-membered rings with one trigonal C atom don’t count here) react in such a way that the product becomes an axially substituted chair.
- Bicyclic compounds react on the outside face.
- Reaction on the more hindered face can be encouraged by: (1) tethered nucleophiles or (2) cyclic transition states (tethered reagents).

Diastereoselectivity in compounds without rings is different: it is less well controlled because there are many more conformations available to the molecule. But even in acyclic compounds rings can still be important, and some of the best diastereoselectivities arise when there is a ring formed temporarily in the transition state of the reaction. With or without cyclic transition states, in some cases we have good prospects of predicting which diastereoisomer will be the major reaction product, or explaining the diastereoselectivity if we already know this. That is the subject of the next chapter.

Further reading

The elegant work of Jeffrey Aubé, describing the selective formation of substituted piperidines by control of their conformation, is in *Angew. Chem. Int. Ed.* 2011, 50, 2734.

Check your understanding

To check that you have mastered the concepts presented in this chapter, attempt the problems that are available in the book’s Online Resource Centre at [http://www.oxfordtextbooks.co.uk/orc/clayden2e/](http://www.oxfordtextbooks.co.uk/orc/clayden2e/)
Looking back

You have had two chapters in a row about stereochemistry: this is the third, and it is time for us to bring together some ideas from earlier in the book. We aim firstly to help you grasp some important general concepts and secondly to introduce some principles in connection with stereoselective reactions in acyclic systems. But, first, some revision.

We introduced the stereochemistry of structures in Chapter 14. We told you about two types of stereoisomers.

● Enantiomers and diastereoisomers
  • Enantiomers—stereoisomers that are mirror images of one another.
  • Diastereoisomers—stereoisomers that are not mirror images of one another.

In this chapter we shall talk about how to make compounds as single diastereoisomers. Making single enantiomers is treated in Chapter 41. Chapter 32 was also about making single diastereoisomers, and we hope that, having read that chapter, you are used to thinking stereochemically. We shall meet two different ways of making single diastereoisomers.

● Reactions that make single diastereoisomers
  • Stereospecific reactions—reactions where the mechanism means that the stereochemistry of the starting material determines the stereochemistry of the product and there is no choice involved.
  • Stereoselective reactions—reactions where one stereoisomer of product is formed predominantly because the reaction has a choice of pathways, and one pathway is more favourable than the other.
These terms were introduced in Chapter 17 in connection with elimination reactions, and many of the reactions we mention will be familiar from earlier chapters (particularly Chapters 15–19, 25, and 26). A common misapprehension is that stereospecific means merely very stereoselective. It doesn’t—the two terms describe quite different properties of the stereochemistry of a reaction. For the purposes of making a single diastereoisomer, you can think of stereospecific reactions as ones which simply exchange different forms of stereochemical ‘currency’ (double bond geometry and three-dimensional relative stereochemistry, for example) while stereoselective reactions create additional new stereochemical value.

Making single diastereoisomers using stereospecific reactions of alkenes

The essence of the definition we have just stated is much easier to grasp with some familiar examples. Here are two.

- $S_{N}2$ reactions are stereospecific: they proceed with inversion so that the absolute stereochemistry of the starting material determines the absolute stereochemistry of the product.

  ![SN2 reaction](image)

- E2 reactions are stereospecific: they proceed through an anti-periplanar transition state, with the relative stereochemistry of the starting material determining the geometry of the product.

  ![E2 reaction](image)

Both of these examples are interesting because they show how, once we have some stereochemistry in a molecule, we can change the functional groups but keep the stereochemistry—this is the essence of a stereospecific reaction. In the second example, we change the bromide to a double bond, but we keep the stereochemistry (or ‘stereochemical information’) because the geometry of the double bond tells us which bromide we started with.

This is a good place to begin if we want to make single diastereoisomers because we can reverse this type of reaction: instead of making a single geometry of alkene from a single diastereoisomer, we make a single diastereoisomer from a single geometry of double bond. Here is an example of this—again, one you have already met (Chapter 19). Electrophilic addition of bromine to alkenes is stereospecific and leads to anti addition across a double bond. So if we want the anti dibromide we choose to start with the trans double bond; if we want the syn dibromide we start with the cis double bond. The geometry of the starting material determines the relative stereochemistry of the product.

![Interactive mechanism for stereospecific anti addition to alkenes](image)

Iodolactonization has a similar mechanism; notice how in these two examples the geometry of the double bond in the starting material defines the relative stereochemistry highlighted in black in the product.
For a stereospecific alkene transformation, choose the right geometry of the starting material to get the right diastereoisomer of the product. Don’t try to follow any ‘rules’ over this—just work through the mechanism.

Now for some examples with epoxides. Epoxides are very important because they can be formed stereospecifically from alkenes: cis alkenes give cis (or syn) epoxides and trans alkenes give trans (or anti) epoxides.

Epoxides also react stereospecifically because the ring-opening reaction is an S\textsubscript{N}2 reaction. A single diastereoisomer of epoxide gives a single diastereoisomer of product.

Leukotrienes
Leukotrienes are important molecules that regulate cell and tissue biology. Leukotriene C\textsubscript{4} (LTC\textsubscript{4}) is a single diastereoisomer with an anti 1,2,S,O functional group relationship. In nature, this single diastereoisomer is made by an epoxide opening: since the opening is S\textsubscript{N}2 the epoxide must start off anti and, indeed, the epoxide precursor is another leukotriene, LTA\textsubscript{4}.

When Corey was making these compounds in the early 1980s he needed to be sure that the relative stereochemistry of LTC\textsubscript{4} would be correctly controlled, and to do this he had to make a trans epoxide. Disconnecting LTA\textsubscript{4} led back to a simpler epoxide.

The trans allylic alcohol needed to make this compound was made using one of the methods we introduced in Chapter 27: reduction of an alkynyl alcohol with LiAlH\textsubscript{4}. Here is the full synthesis: alkylation of an ester enolate with prenyl bromide gives a new ester, which itself is turned into an alkylating agent by reduction and tosylation. The alkyne is introduced as its lithium derivative with the alcohol protected as a THP acetal. Hydrolysis of the acetal with
aqueous acid gives the hydroxy-alkyne needed for reduction to the \( E \) double bond, which is then epoxidized.

**Stereoselective reactions**

For most of the rest of the chapter we shall discuss stereoselective reactions. You have already met several examples and we start with a summary of the most important methods.

- **E1** reactions are stereoselective: they form predominantly the more stable alkene.
- Nucleophilic attack on six-membered ring ketones is stereoselective: small nucleophiles attack axially and large ones equatorially.

- Alkylation of cyclic enolates is stereoselective, with reaction taking place on the less hindered face (four- or five-membered rings) or via axial attack (six-membered rings).

- Epoxidation of cyclic alkenes is stereoselective, with reaction taking place on the less hindered face, or directed by hydrogen bonding to a hydroxyl group.

**A comment on structural drawings of single diastereoisomers**

In the two reactions just above, a racemic starting material gives a racemic product as a single diastereoisomer. It is easy to draw a racemic compound with just one stereogenic centre—we just avoid showing stereochemistry. But in the products we have to show relative stereochemistry because we need to indicate which diastereoisomer is formed. There is no way of doing this except by arbitrarily choosing one enantiomer and drawing that. If there is a danger of confusion, we might sometimes write ‘(±)’ under the structure.
Prochirality

Take another look at the reactions in the chapter so far—in particular those that give single diastereoisomers (rather than single enantiomers or geometrical isomers), in other words, those that are diastereoselective. They all involve the creation of a new, tetrahedral stereogenic centre at a carbon that was planar and trigonal. This leads us to our first new definition. Trigonal carbons that aren’t stereogenic (or chiral) centres but can be made into them are called prochiral.

At the very start of Chapter 15 we introduced stereochemistry by thinking about the reactions of two sorts of carbonyl compounds. They are shown again here: the first has a prochiral carbonyl group. The second, on the other hand, is not prochiral because no stereogenic centre is created when the compound reacts.

A tetrahedral carbon atom can be prochiral too—if it carries two identical groups (and so is not a chiral centre) but replacement of one of them leads to a new chiral centre, then the carbon is prochiral.

Glycine is the only common α amino acid without a chiral centre, but replacing one of the two protons on the central carbon with, say, deuterium creates one: the CH₂ carbon is prochiral. Similarly, converting a malonate derive into its monoester makes a chiral centre where there was none: the central C is prochiral. Now, does this ring any bells? It should remind you very much of the definitions in Chapter 31 of enantiotopic and diastereotopic in connection with NMR spectra. Replacing one of two enantiotopic groups with another group leads to one of two enantiomers; replacing one of two diastereotropic groups with another group leads to
one of two diastereoisomers. Diastereotopic groups are chemically different; enantiotopic
groups are chemically identical.

Exactly the same things are true for the faces of a prochiral carbonyl group or double bond.
If reaction on one of two faces of the prochiral group generates one of two enantiomers, the
faces are enantiotopic; if the reaction generates one of two diastereoisomers, the faces are
diastereotopic. We will now apply this thinking to the first few reactions in this chapter: they
are shown again below. The two examples in the top row have prochiral C=C or C=O bonds
with diastereotopic faces: choosing which face of the double bond or carbonyl group to react
on amounts to choosing which diastereoisomer to form. In the third example, the faces of the
prochiral carbonyl group are enantiotopic: choosing which face to attack amounts to choos-
ing which enantiomer to form. In the fourth example, the two faces of C=O are homotopic:
an identical product is formed whichever face is attacked.

Knowing this throws some new light on the last chapter. Almost without exception, every
stereoselective reaction there involved a double bond (usually C=C, sometimes C=O) with
diastereotopic faces. The diastereotopic faces were distinguished by steric hindrance, or
by a nearby hydrogen-bonding group, and so were able to react differently with an incoming
reagent.

Using an R/S-type system to name prochiral faces and groups

Just as stereogenic centres can be described as R or S, it is possible to assign labels to the enantiotopic groups at pro-
chiral tetrahedral carbon atoms or the enantiotopic faces of prochiral trigonal carbon atoms. The basis of the system is
the usual R,S system for stereogenic centres, but pro-R and pro-S are used for groups and Re and Si for faces.
Pro-R and pro-S can be assigned to a pair of enantiotopic groups simply by using the usual rules to assign R or S to the centre
created if the group in question is artificially elevated to higher priority than its enantiotopic twin. We’ll use G to replace H as
we did in Chapter 31: just assume that G has priority immediately higher than H. The method is illustrated for glycine.
Faces of a prochiral trigonal carbon atom are assigned Re and Si by viewing the carbon from that side and counting down the groups in priority 1–3. Counting round to the right (clockwise) means the face is Re; counting round to the left (anticlockwise) means it’s Si. Remember our advice from Chapter 14: think of turning a steering wheel in the direction of the numbers: does the car go to the right or the left?

Like R and S, these stereochemical terms are merely labels: they are of no consequence chemically.

Just like diastereotopic signals in an NMR spectrum, diastereotopic faces are always different in principle, but sometimes not so in practice. The very first reaction of Chapter 32 is a case in point: this C=O group has two diastereotopic faces, which, due to free rotation about single bonds, average out to about the same reactivity, so we cannot expect any reasonable level of diastereoselectivity.

We put Chapter 32 first because in rings conformation is well defined, and this ‘averaging’ effect is held at bay. We are about to let it out again, but we will show you how it can be tamed to surprisingly good effect.

**Additions to carbonyl groups can be diastereoselective even without rings**

What happens if we bring the stereogenic centre closer to the carbonyl group than it was in the last example? You might expect it to have a greater influence over the carbonyl group’s reactions. And it does. Here is an example.

There is three times as much of one of the two diastereisomeric products as there is of the other, and the major (anti) diastereoisomer is the one in which the nucleophile has added to the front face of the carbonyl group as drawn here. We can make these same two diastereomers by addition of an organometallic to an aldehyde. For example, this Grignard reagent gives three times as much of the syn diastereoisomer as the anti diastereoisomer. The major product has changed, but the product still arises from attack on the front face of the carbonyl as shown.
Drawing diastereoisomers of acyclic molecules

The three structures below all show the same diastereoisomer (the major product from the last reaction), but in three different conformations (we are just rotating about a bond to get from one to another).

Which is the best? A good guideline, which we suggested in Chapter 14, is to place the longest carbon chain zig-zagging across the page in the plane of the paper, and allow all the smaller substituents to extend above or below that chain. The first structure here is drawn like that. But this is only a guideline, and the second structure here is a bit more informative regarding the reaction because, when it is drawn like this, you can clearly see from which direction the ethyl group has attacked the carbonyl. Our advice would be that you first of all draw the product of any reaction in more or less the same conformation as the starting material to ensure you make no mistakes, and then rotate about a single bond to place the longest chain in the plane of the paper.

If you still have problems manipulating structures mentally—for example, if you find it hard to work out whether the substituents that aren’t in the plane should be in front of or behind the page—build some models.

These two reactions are not nearly as diastereoselective as most of the reactions of cyclic compounds you met in the last chapter. But we do now need to explain why they are diastereoselective at all, given the free rotation possible in an acyclic molecule. The key, as much with acyclic as with cyclic molecules, is conformation.

The conformation of a chiral aldehyde

What will be the conformation of the aldehyde in the margin? Using the principles we outlined in Chapter 16, we can expect it to be staggered, with no eclipsing interactions, and also with large substituents as far apart from one another as possible. A Newman projection of one of the possible conformers might look like the one shown in the margin. There are no eclipsing interactions, and the large phenyl group is held satisfactorily far away from the O and the H atoms of the aldehyde.

By rotating about the central bond of the aldehyde (the one represented by a circle in the Newman projection) we can suggest a series of possible conformations. Provided we move in 60° steps, none of them will have any eclipsing interactions. The full set of six conformers is shown here. Look at them for a moment and notice how they differ.

Only two of them, boxed in orange, place the large Ph group perpendicular to the carbonyl group. These yellow-boxed conformations are therefore the lowest-energy conformers and, for the purpose of the discussion that follows, they are the only ones whose reactions we need to consider.
Lowest-energy conformations of a carbonyl compound

The most important conformations of a carbonyl compound with a stereogenic centre adjacent to the carbonyl group are those that place the largest group perpendicular to the carbonyl group.

\[
\begin{align*}
\text{L} &= \text{large group, e.g. Ph} \\
\text{M} &= \text{medium-sized group, e.g. Me} \\
\text{S} &= \text{small group, e.g. H}
\end{align*}
\]

The major product arises from the most reactive conformer

Now that we have decided which are the important conformations, how do we know which gives the product? We need to decide which is the most reactive. All we need to do is to remember that any nucleophile attacking the carbonyl group will do so from the Bürgi–Dunitz angle—about 107° from the \( \text{C}=\text{O} \) bond. The attack can be from either side of \( \text{C}=\text{O} \), and the following diagrams show the possible trajectories superimposed on the two conformations we have selected, which are in equilibrium with one another.

The black flight path is the best and the three brown flight paths are hindered by Ph or Me

Not all four possible ‘flight paths’ for the nucleophile are equally favourable. For the three shown in brown, the nucleophile passes within 30° or so of another substituent. But, for the one shown in black, there is no substituent nearby except \( \text{H} \) to hinder attack: the conformation on the left is the most reactive one, and it reacts to give the diastereoisomer shown below.

In order to avoid making mistakes, we suggest you:

- first draw the product in a conformation similar to that of the starting material
- then redraw to put the longest chain in the plane of the paper.

Here, this just means drawing the view from the top of the Newman projection—there is no need to rotate any bonds in this case.

With \( \text{Nu}=\text{Et} \) we have the right product and, more importantly, we can be pretty sure it is for the right reason: this model of the way a nucleophile attacks a carbonyl compound, called the Felkin–Anh model, is supported by theoretical calculations and numerous experimental results. Notice that we don’t have to decide which is the lower energy of the two conformations: this is not necessary because the attack in black will occur even if the conformer on the left is the minor one in the mixture.
The same reasoning accounts for the diastereoselectivity of the reduction on p. 858: first we need to draw the two important conformers of the ketone; the ones that have the large group (Ph) perpendicular to the C=O group.

Now choose the angle of attack that is the least hindered and draw a Newman projection of the product. Finally, redraw the Newman projection as a normal structure, preferably with the longest chain in the plane of the paper.

**The effect of electronegative atoms**

One of the most powerful anticancer agents known is dolastatin, isolated from the sea-hare *Dolabella*. Dolastatin contains an unusual amino acid, with three stereogenic centres, and chemists in Germany managed to exploit Felkin–Anh control very effectively to make it from the much more widespread amino acid isoleucine. This is the sequence of reactions.

![Interactive Felkin–Anh model for ketone reduction](image)

The key step is the aldol reaction of the enolate of methyl acetate with the protected amino aldehyde. To rationalize the stereoselectivity, we first need to draw the two most important conformations of this aldehyde with the large group perpendicular to C=O. The trouble is, which do we choose as ‘large’: the NBn2 group or the branched alkyl group? Since we know which diastereoisomer is produced we can work backwards to find that it must be the NBn2 group that sits perpendicular to C=O in the reactive transition state, and not alkyl. We can draw the best conformation without worrying about alternatives.

Now look at the diastereoselectivity of the reaction: it is much greater than the 3:1 we saw before—more like 20:1. This really does suggest that there is a further factor at work here, and that further factor is the electronegative N atom.

Carbonyl groups increase the reactivity of adjacent leaving groups towards nucleophilic substitution by several orders of magnitude. This was an effect that we noted in Chapter 15, where we showed that the ketone below reacts by the SN2 mechanism 5000 times as fast as methyl chloride itself. We explained this effect by saying that the $\pi^*$ of the C=O and the $\sigma^*$ of C–Cl overlap to form a new, lower-energy (and therefore more reactive) LUMO. What we did not
note then, because it was not relevant, is that this overlap can only occur when the C–Cl bond is perpendicular to the C=O bond, because only then are the \( \pi^* \) and \( \sigma^* \) orbitals aligned correctly.

The same thing happens even with electronegative atoms X that are not leaving groups in the \( S_N2 \) reaction (for example, \( X=OR, NR_2, SR, \) etc.). The \( \pi^* \) and \( \sigma^* \) orbitals add together to form a new, lower-energy molecular orbital, more susceptible to nucleophilic attack. But, if \( X \) is not a leaving group, attack on this orbital will result not in nucleophilic substitution but in addition to the carbonyl group. Again, this effect will operate only when the C–X and C=O bonds are perpendicular so that the orbitals align correctly.

What does this mean for stereoselectivity? Conformations of the chiral carbonyl compound that place an electronegative atom perpendicular to the C=O bond will be more reactive—size doesn’t matter. So, in the dolastatin amino acid example, the conformations with NBn2 perpendicular to C=O are the only conformations we need to consider.

**Using the Felkin–Anh model**

To predict or explain the stereoselectivity of reactions of a carbonyl group with an adjacent stereogenic centre, use the Felkin–Anh model. If you look at the next example, just below this box, you can follow exactly the series of steps we suggest you take:

- Draw Newman projections of the conformations of the starting material that place a large group or an electronegative group perpendicular to C=O.
- Allow the nucleophile to attack along the least hindered trajectory, taking into account the Bürgi–Dunitz angle.
- Draw a Newman projection of the product that arises from attack in this way.
- Carefully flatten the Newman projection on to the page to produce a normal structure, preferably with the longest chain of C atoms in the plane of the page. Check that you have done this last step correctly; it is very easy to make mistakes here. Use a model if necessary, or do the ‘flattening out’ in two stages—first view the Newman projection from above or below and draw that; then rotate some of the molecule about a bond if necessary to get the long chain into the plane of the page.

**Chelation can reverse stereoselectivity**

\[
\begin{align*}
\text{Ph} & \quad \text{SMe} \\
\text{O} & \quad \text{Li}^+ \text{R}_3\text{BH}^+ \\
\text{Ph} & \quad \text{SMe} \\
\text{OH} & \quad \text{Li}^+ \text{R}_3\text{BH}^+
\end{align*}
\]
You should now be in a position to explain the outcome of this reaction without much difficulty. Sulfur is the electronegative atom, so the conformations we need to consider are the two following. Unhindered attack on the second gives the diastereoisomer shown.

But, from what we have told you so far, the next reaction would present a problem: changing the metal from lithium to zinc has reversed the stereoselectivity. Using the simple Felkin–Anh model no longer works: it gives the wrong answer.

The reason is that zinc can chelate sulfur and the carbonyl group. Chelation is the coordination of two heteroatoms carrying lone pairs to the same metal atom, and here it changes the conformation of the starting material. No longer does the most reactive or most populated conformation place the electronegative S atom perpendicular to C=O; instead it prefers S to lie as close to the carbonyl oxygen as possible so that Zn can bridge between S and O, like this:

When chelation is possible, this is the conformation to consider—the one with the carbonyl O and the other chelating atom almost eclipsing one another. It is the most populated because it is stabilized by the chelation, and it is also the most reactive, because the Lewis-acidic metal atom increases the reactivity of the carbonyl group. Attack is still along the less hindered pathway, but this now leads to the other face of the carbonyl group, and the stereochemical outcome is reversed.

Two things are needed for chelation to occur:

- a heteroatom with lone pairs available for coordination to a metal
- a metal ion that prefers to coordinate to more than one heteroatom at once—these are mainly more highly charged ions, as shown in the table.

Here is another example of a reversal in selectivity that can be explained using a non-chelated Felkin–Anh model with Na⁺ and a chelated model with Mg²⁺.

Not only does chelation control reverse the stereoselectivity, it gives a much higher degree of stereoselectivity. Stereoselectivities in chelation-controlled additions to C=O groups are typically >95:5. But this fits in nicely with the ideas we presented at the end of the last chapter: stereoselectivity is likely to be high if a cyclic transition state is involved. Chelation involves
just such a transition state, so it should be no surprise that it lets us achieve much higher levels of control than the acyclic Felkin–Anh model does.

**Chelation, rate, and stereoselectivity**

The correlation of rate of addition with diastereoselectivity was demonstrated in a series of experiments that involved reacting Me₂Mg with protected α-hydroxy-ketones. As the protecting group was changed from a methyl ether to a trimethylsilyl ether and then through a series of increasingly bulky silyl ethers, both the rate of the reaction and the diastereoselectivity decreased. With small protecting groups the reaction takes place through the chelated transition state—the selectivity shows this—and the rate is faster because of the activating effect of the Lewis-acidic magnesium ion. But with larger protecting groups chelation of Mg⁺⁺ between the two oxygen atoms is frustrated: the rate drops off and the selectivity becomes more what would be expected from the Felkin–Anh model.

- **Chelation:**
  - may change the direction of diastereoselectivity
  - leads to high levels of diastereoselectivity
  - increases the rate of the addition reaction.

Chelation is possible through six- as well as five-membered rings and the reduction of the ketone below is a nice example of the reversal of diastereoselectivity observed when chelating Ce³⁺ ions are added to a normal sodium borohydride reduction. The products were important for making single geometrical isomers of alkenes in a modification of the Wittig reaction. Notice too that the rate changes: with Ce³⁺ the reaction can be done at –78°C.

**Attack on α chiral carbonyl compounds: summary**

The flow chart summarizes what you should consider when you need to predict or explain the stereochemical outcome of nucleophilic attack on a chiral carbonyl compound.

- **is there a heteroatom at the chiral centre?**
  - yes
  - no

- **is there a metal ion capable of chelation with the heteroatom?**
  - yes
  - no

- **use Felkin–Anh model:**
  - consider reactions on conformations with largest group perpendicular to C=O
  - consider reactions on conformations with most electronegative atom perpendicular to C=O

- **use chelation model:**
  - consider reactions on conformation with C=O and heteroatom held close in space

---

**Stereoselective reactions of acyclic alkenes**

Earlier in the chapter we discussed how to make single diastereoisomers by stereospecific additions to double bonds of fixed geometry. But if the alkene also contains a chiral centre there will be a stereoselective aspect to its reactions too: its faces will be diastereotopic, and there will be two possible outcomes even if the reaction is fully stereospecific. Here is an example where the reaction is an epoxidation.

**The Houk model**

In order to explain reactions of chiral alkenes like this, we need to assess which conformations are important and consider how they will react, just as we have done for chiral carbonyl compounds. Much of the work on alkene conformations was done by K. N. Houk using theoretical computer models, and we will summarize the most important conclusions of these studies. The theoretical studies looked at two model alkenes, shown in the margin.

The calculations found that the low-energy conformations in each case were those in which a substituent eclipses the double bond. For the simple model alkene 1, the lowest-energy conformation is the one that has the proton in the plane of the alkene. Another low-energy conformation—only 3.1 kJ mol⁻¹ higher—has one of the methyl groups eclipsing the double bond, so that when we start looking at reactions of this type of alkene, we shall have to consider both conformations.

K. N. Houk works at the University of California in Los Angeles. He has provided explanations for a number of stereochemical results by using powerful computational methods.
model alkene 1 has two low-energy conformations

```
Me

Me
```

lowest energy: H eclipses plane of double bond

```
Me

Me
```

slightly higher energy: Me eclipses plane of double bond

model alkene 2 has only one low-energy conformation

```
Me

Me
```

only important conformer:
H eclipses double bond

```
Me

Me
```

high-energy conformation
due to Me–Me interaction

For the model alkene 2, with a cis substituent, the conformation is more predictable and the only low-energy conformer is the one with the hydrogen eclipsing the double bond. There is no room for a methyl group to eclipse the double bond because if it did it would get too close to the cis substituent at the other end of the double bond.

The message from the calculations is this:

- The lowest-energy conformation of a chiral alkene will have H eclipsing the double bond.
- If there is a cis substituent on the alkene, this will be the only important conformation; if there is no cis substituent, other conformations may be important too.

Now we can apply the theoretical model to some real examples.

**Stereoselective epoxidation**

We started this section with a diastereoselective epoxidation of an alkene. The alkene was this one, and it has a substituent cis to the stereogenic centre. We can therefore expect it to have one important conformation, with H eclipsing the double bond. When a reagent—m-CPBA here—attacks this conformation, it will approach the less hindered face, and the outcome is shown.

```
Me

SiMe2Ph
```

cis-substituted alkene
only important conformer
has H eclipsing double bond

```
m-CPBA attacks the
less hindered face
```

>95% one diastereoisomer

Without the cis substituent, selectivity is much lower.

```
SiMe2Ph
```

```
m-CPBA
```

```
+ SiMe2Ph
```

61:39 ratio of diastereoisomers

*m*-CPBA still attacks the less hindered face of the alkene, but with no cis substituent there are two low-energy conformations: one with H eclipsing the double bond, and one with Me eclipsing. Each gives a different stereochemical result, explaining the low stereoselectivity of the reaction.
You saw at the end of the last chapter that the reactions of $m$-CPBA can be directed by hydroxyl groups, and the same thing happens in the reactions of acyclic alkenes. This allylic alcohol epoxidizes to give a 95:5 ratio of diastereoisomers.

![Diagram]

Drawing the reactive conformation explains the result. The thing that counts is the cis methyl group: the fact that there is a trans one too is irrelevant as it is just too far away from the stereogenic centre to have an effect on the conformation. The reaction uses a racemic mixture, but to explain the diastereoselectivity we just have to pick one enantiomer and show what happens to that.

- **To explain the stereoselectivity of reactions of chiral alkenes:**
  - Draw the conformation with H eclipsing the double bond.
  - Allow the reagent to attack the less hindered of the two faces or, if coordination is possible, to be delivered to the face syn to the coordinating group.
  - Draw the product in the same conformation as the starting material.
  - Redraw the product as a normal structure with the longest chain in the plane of the paper.

**Stereoselective enolate alkylation**

Chiral enolates can be made from compounds with a stereogenic centre β to a carbonyl group. Once the carbonyl is deprotonated to form the enolate, the stereogenic centre is next to the double bond and in a position to control the stereoselectivity of its reactions. The scheme below shows stereoselectivity in the reactions of some chiral enolates with methyl iodide.
The enolate is a cis-substituted alkene because either O or OEt must be cis to the stereogenic centre, so that to explain the stereoselectivity we need consider only the conformation with H eclipsing the double bond. Notice how the diastereoselectivity increases as the group R gets bigger because there is then more contrast between the size of Me and R. In each case, the electrophile adds to the less hindered face, opposite R.

The other diastereoisomer can be made just by having the methyl group in place first and then protonating the enolate. The selectivities are lower (because a proton is small), but this does illustrate the way in which reversing the order of introduction of two groups can reverse the stereochemical outcome of the reaction.

**Aldol reactions can be stereoselective**

In Chapter 26 you met the aldol reaction: reaction of an enolate with an aldehyde or a ketone. Many of the examples you saw approximated to this general pattern.

Only one new stereogenic centre is created, so there is no question of diastereoselectivity. But with substituted enolates, two new stereogenic centres are created and we need to be able to predict which diastereoisomer will be formed. Here is an example from p. 626. We did not consider stereochemistry at that stage, but we can now reveal that the syn diastereoisomer is the major product of the reaction.

The important point about substituted enolates is that they can exist as two geometrical isomers, cis or trans. Which enolate is formed is an important factor controlling the diastereoselectivity because it turns out that, in many examples of the aldol reaction, cis enolates give syn aldols preferentially and trans enolates give anti aldols preferentially.
Diastereoselectivity in aldol reactions

Generally (but certainly not always!) in aldol reactions:

\[
\begin{align*}
\text{cis enolate} & \quad \text{syn aldol} \\
\text{trans enolate} & \quad \text{anti aldol}
\end{align*}
\]

Let’s start by showing some examples and demonstrating how we know this to be the case. Some enolates can exist only as \text{trans} enolates because they are derived from cyclic ketones. This enolate, for example, reacts with aldehydes to give only the \text{anti} aldol product.

If we choose the group ‘X’, next to the carbonyl group, to be large, then we can be sure of getting just the \text{cis} enolate. So, for example, the lithium enolate of this \text{t}-butyl ketone forms just as one geometrical isomer, and reacts with aldols to give only the \text{syn} aldol product.

\[
\begin{align*}
\text{cis enolate keeps Me and t-Bu apart} & \quad \text{syn aldol}
\end{align*}
\]

\textit{cis and trans, E and Z, syn and anti}

Before going further, there are two points we must clarify. The first is a problem of nomenclature, and concerns the enolates of esters. Here are two closely related ester enolate equivalents, drawn with the same double bond geometry.

\[
\text{The answer is both! For the Li enolate, the usual rule makes OLi of lower priority than OMe (because Li has a smaller atomic number than C), so it’s E, while the silyl enol ether (or ‘silyl ketene acetal’) has OSi of higher priority than OMe (Si has a larger atomic number than C), so it’s Z. This is merely a nomenclature problem, but it would be irritating to have to reverse all our arguments for lithium and boron enolates (as opposed to, say, tin or silicon ones). So, for the sake of consistency, it is much better to avoid the use of E and Z with enolates and instead use cis and trans, which then always refer to the relationship between the substituent and the anionic oxygen (bearing the metal).}

The other point concerns \textit{syn} and \textit{anti}. We said earlier that there is no precise definition of these terms: they are a useful way of distinguishing two diastereoisomers provided the structure of at least one of them is presented in diagrammatic form. For aldol products the convention is that \textit{syn} or \textit{anti} refers to the enolate substituent (the green Me in the last example) and the new hydroxyl group, provided the main chain is in the plane of the paper, the way we have encouraged you to draw molecules.

The aldol reaction has a chair-like transition state

These are the experimental facts: how can we explain them? Aldol reactions are another class of stereoselective process with a cyclic transition state. During the reaction, the lithium is transferred from the enolate oxygen to the oxygen of the carbonyl electrophile. This is represented in the margin both in curly arrow terms and as a transition state structure. A six-membered ring is involved, and we can expect this ring to adopt more or less a chair
conformation. The easiest way to draw this is first to draw the chair, and then convert atoms to O or Li as necessary. Here it is.

In drawing this chair, we have one choice: do we allow the aldehyde to place R equatorial or axial? Both are possible but, as you should now expect, there are fewer steric interactions if R is equatorial. Note that the enolate doesn’t have the luxury of choice. If it is to have three atoms in the six-membered ring, as it must, it can do nothing but place the methyl group pseudoaxial. The aldol formed from the favoured transition state structure, with R pseudoaxial, is shown below—first in the conformation of the transition state, and then flattened out on to the page, and it is anti.

We can do the same for the cis enolate. The enolate has no choice but to put its methyl substituent pseudoaxial, but the aldehyde can choose either pseudoaxial or pseudoequatorial. Again, pseudoaxial is better and the reaction gives the product shown—the syn aldol.

Stereoselective enolization is needed for stereoselective aldols

The cyclic transition state explains how enolate geometry controls the stereochemical outcome of the aldol reaction. But what controls the geometry of the enolate? For lithium enolates of ketones the most important factor is the size of the group that is not enolized. Large groups force the enolate to adopt the cis geometry; small groups allow the trans enolate to form. Because we can’t separate the lithium enolates, we just have to accept that the reactions of ketones with small R will be less diastereoselective.

With boron enolates, we don’t have to rely on the structure of the substrate—we choose the groups on boron—and we can get either cis or trans depending on which groups these are. Boron enolates are made by treating the ketone with an amine base (often Et₂N or i-PrNEt₂) and R₂B–X, where X⁻ is a good leaving group such as chloride or triflate (CF₃SO₃⁻). With bulky
groups on boron, such as two cyclohexyl groups, a trans enolate forms from most ketones. The boron enolate reacts reliably with aldehydes to give anti aldol products through the same six-membered transition state that you saw for lithium enolates.

\[ \text{Ph} \quad \text{O} \quad \text{O} \quad \text{ClB(c-Hex)}_2 \quad \text{B(c-Hex)}_2 \quad \text{Ph} \quad \text{OH} \quad \text{RCHO} \quad \text{ClB(c-Hex)}_2 \]

With smaller B substituents, the cis enolate forms selectively. Here, the boron is part of a bicyclic structure known as 9-BBN (9-borabicyclononane). The bicyclic part may look large but, as far as the rest of the molecule is concerned, it’s ‘tied back’ behind the boron, and the methyl group can easily lie cis to oxygen. The cis enolate then gives syn aldol products. Di-n-butyliboron triflate (Bu₂BOTf) also gives cis enolates.

\[ \text{Ph} \quad \text{O} \quad \text{Ph} \quad \text{O} \quad \text{Et₃N} \quad \text{Ph} \quad \text{O} \quad \text{R} \quad \text{OH} \quad \text{RCHO} \quad \text{B} \quad \text{TfO} \quad \text{B} \]

**Summary: How to make syn and anti aldols**

To make syn aldols of ketones:
- use boron enolate with 9-BBN-OTf or Bu₂BOTf
- from a ketone RCOEt with bulky R, use lithium enolate

To make anti aldols of ketones:
- use boron enolate with (c-Hex)₂BCl
- from a cyclic ketone, use lithium enolate

---

**Single enantiomers from diastereoselective reactions**

The aldol reactions in the last section made single diastereoisomers from two achiral compounds. No enantiomerically pure reagents were used, so the reaction had no choice but to give the product diastereoisomer as a racemic mixture of its two enantiomers.

In all the other diastereoselective reactions in this chapter, the starting material has been chiral, with the formation of new chiral centres controlled by the configuration of the starting material. Whatever the diastereoselectivity of the reaction, if the starting material is racemic, so will be the product; if the starting material is enantiomerically pure, so will be the product. The epoxidation of the allylic alcohol in the margin illustrates this point.

The reaction starts with racemic material (no stereochemistry is shown at the chiral centre) and makes a racemic product. Of course we have only drawn one enantiomer—the only way to draw one diastereoisomer is to choose one enantiomer and draw that—but the indication ‘±’ underneath tells you to expect an equal amount of the other enantiomer as well. Even without this indication, you should be able to work out, in any given case, whether a compound is racemic or not, providing you know where it comes from. Here the starting material is racemic and the reagent is achiral so the product must be racemic.

The example of this reaction earlier in the chapter (p. 856) was this type of reaction. The starting alcohol was racemic and the product was just one racemic diastereoisomer—the all cis compound. But if the starting material had been enantiomerically pure, so would the product. One enantiomer gives one enantiomer of the product: the other enantiomer of the alcohol...
gives the other. Both products are the same diastereoisomer (all cis) but they are mirror images of each other. If you start with enantiomerically pure compounds, the products will be enantiomerically pure as well.

We gave an example of this during the discussion of the Felkin–Anh model. The starting material was the natural amino acid isoleucine and was the enantiomer shown. The product of the aldol reaction was therefore also a single enantiomer. The original chiral centre in both these examples is not affected by the reaction and remains unchanged.

It is much more useful to make enantiomerically pure as well as diastereoisomerically pure compounds, particularly in the synthesis of a drug. The strategy used here is to make the starting material from an enantiomerically pure compound available from nature: in this case an amino acid. These available enantiomerically pure compounds are known collectively as the chiral pool. You can read more about this in Chapter 41 on asymmetric synthesis.

If you are making an enantiomerically pure compound with more than one stereogenic centre, only one needs be borrowed from the chiral pool, provided diastereoselective reactions can be used to introduce the others with control over relative stereochemistry. Because the first chiral centre has defined absolute configuration, any diastereoselective reaction that controls the relative stereochemistry of a new chiral centre also defines its absolute configuration.
